Abstract

Improving sample efficiency has been a longstanding goal in reinforcement learning. This paper proposes VRMPO algorithm: a sample efficient policy gradient method with stochastic mirror descent. In VRMPO, a novel variance-reduced policy gradient estimator is presented to improve sample efficiency. We prove that the proposed VRMPO needs only $O(\epsilon^{-4})$ sample trajectories to achieve an $\epsilon$-approximate first-order stationary point, which matches the best sample complexity for policy optimization. Extensive empirical results demonstrate that VRMPO outperforms the state-of-the-art policy gradient methods in various settings.

Introduction

Policy gradient (Williams 1992; Sutton et al. 2000) is widely used to search the optimal policy in reinforcement learning (RL), and it has achieved significant successes in challenging fields such as playing Go (Silver et al. 2016, 2017) or robotics (Duan et al. 2016). However, policy gradient methods suffer from high sample complexity, since many existing popular methods require to collect a lot of samples for each step to update its parameters (Haarnoja et al. 2018; Yang et al. 2021; Xing et al. 2021; Yang et al. 2022), which partially reduces the effectiveness of the samples. Besides, it is still very challenging to provide a theoretical analysis of sample complexity for policy gradient methods instead of empirically improving sample efficiency.

To improve sample efficiency, this paper addresses how to design an efficient and convergent algorithm with stochastic mirror descent (SMD) (Nemirovskij and Yudin 1983). SMD keeps the advantage of low memory requirement and low computational complexity (Lei and Tang 2018), which implies SMD needs less samples to learn a model. However, the significant challenges of applying the existing SMD to RL are two-fold: 1) The objective of policy-based RL is a typical non-convex function, Ghadimi et al. (2016) show that it may cause instability and even divergence when updating the parameter of a non-convex objective by SMD via a single sample. 2) The large variance of policy gradient estimator is a critical bottleneck of improving sample efficiency for policy optimization with SMD. The non-stationary sampling process with the environment will lead to a large variance on the policy gradient estimator (Papini et al. 2018), which requires more samples to get a robust policy gradient and results in poor sample efficiency (Liu et al. 2018).

To address the above challenges, we provide a theory analysis of the dilemma of applying SMD to policy optimization. Result (18) shows that under the Assumption 1, deriving the algorithm directly via SMD can not guarantee the convergence for policy optimization. Furthermore, we propose a new algorithm MP0 that keeps a provable convergence guarantee (see Theorem 2). Designing a new gradient estimator according to historical information of policy gradient is the key to MP0.

Then, we propose a variance-reduced mirror policy optimization algorithm (VRMPO): an efficient sample method via constructing a variance reduced policy gradient estimator. Concretely, we design an efficiently computable policy gradient estimator (see Eq.(26)) that utilizes fresh information and yields a more accurate estimation of the policy gradient, which is the key to improve sample efficiency. Theorem 3 illustrates that VRMPO needs $O(\epsilon^{-4})$ sample trajectories to achieve an $\epsilon$-approximate first-order stationary point ($\epsilon$-FOSP). To our best knowledge, the proposed VRMPO matches the best sample complexity among the existing literature. Particularly, although SRVR-PG (Xu et al. 2020; Xu 2021) achieves the same sample complexity as VRMPO, our approach needs less assumptions than Xu et al. (2020); Xu (2021), and our VRMPO unifies SRVR-PG. Besides, empirical result shows VRMPO converges faster than SRVR-PG.

Background and Stochastic Mirror Descent

Reinforcement learning (RL) is often formulated as Markov decision processes (MDP) $M = (S, A, P, R, \rho_0, \gamma)$, where $S$ is state space, $A$ is action space; $P(s'| s, a)$ is the transition probability of the state transition from $s$ to $s'$ under playing $a$; $R(\cdot, \cdot) : S \times A \rightarrow [-R_{max}, R_{max}]$ is the reward function, where $R_{max}$ is a certain positive scalar. $\rho_0(\cdot) : S \rightarrow [0, 1]$ is the initial state distribution and $\gamma \in (0, 1)$.

Policy $\pi_\theta(a|s)$ is a probability distribution on $S \times A$ with a parameter $\theta \in \mathbb{R}^p$. Let $\tau = \{s_t, a_t, t_{t+1}\}_{t=0}^{H_T}$ be a trajectory, where $s_0 \sim \rho_0(s_0), a_t \sim \pi_\theta(\cdot|s_t), r_{t+1} = R(s_t, a_t), s_{t+1} \sim P(\cdot|s_t, a_t)$, and $H_T$ is the finite horizon of $\tau$. The
expected return function $J(\theta)$ is defined as follows,
\[
J(\theta) = \int_{\tau} P(\tau|\theta) R(\tau) d\tau = \mathbb{E}_{\tau \sim \pi_\theta}[R(\tau)],
\]
where $P(\tau|\theta) = \rho_0(s_0) \prod_{t=0}^{H-1} P(s_{t+1} | s_t, a_t) \rho_t(a_t|s_t)$ is the probability of generating $\tau$, $R(\tau) = \sum_{t=0}^{H-1} \gamma^t r_{t+1}$ is the accumulated discounted return. Let $\mathcal{J}(\theta) = -J(\theta)$, the central problem of policy-based RL is to solve the problem:
\[
\theta^* = \arg \max_\theta J(\theta) \iff \theta^* = \arg \min_\theta \mathcal{J}(\theta). \tag{2}
\]
Computing $\nabla J(\theta)$ analytically, we have
\[
\nabla J(\theta) = \mathbb{E}_{\tau \sim \pi_\theta} \left[ \sum_{t \geq 0} \nabla_g \log \pi_\theta(a_t|s_t) R(\tau) \right]. \tag{3}
\]
Let $g(\tau|\theta) = \sum_{t=0}^{H-1} \nabla_g \log \pi_\theta(a_t|s_t) R(\tau)$, which is an unbiased estimator of $\nabla J(\theta)$. Vanilla policy gradient (VPG) is a straightforward way to solve problem (2) as follows,
\[
\theta \leftarrow \theta + \alpha g(\tau|\theta),
\]
where $\alpha$ is step size.

**Assumption 1.** (Papini et al. 2018) For each pair $(s,a) \in \mathcal{S} \times \mathcal{A}$, $\theta \in \mathbb{R}^n$, and all components $i,j$ there exists positive constants $G,F$ such that:
\[
|\nabla \theta_i \log \pi_\theta(a|s)| \leq G, \quad \left| \frac{\partial^2}{\partial \theta_i \partial \theta_j} \log \pi_\theta(a|s) \right| \leq F. \tag{4}
\]
Assumption 1 implies $\nabla J(\theta)$ is $L$-Lipschitz (Papini et al. 2018, Lemma B.2), i.e.,
\[
||\nabla J(\theta_1) - \nabla J(\theta_2)|| \leq L ||\theta_1 - \theta_2||, \tag{5}
\]
where $L = R_{\max} H \left( H G^2 + F \right) / (1 - \gamma)$. Besides, under Assumption 1, Shen et al. (2019) have shown the property:
\[
||g(\tau|\theta) - \nabla J(\theta)||^2 \leq G^2 R_{\max}^2 / (1 - \gamma)^4 =: \sigma^2. \tag{6}
\]

**SMD and Bregman Gradient**

Now, we review some basic concepts of stochastic mirror descent(SMD) and Bregman gradient.

Let’s consider the stochastic optimization problem,
\[
\min_{\theta \in D_\theta} \{ f(\theta) = \mathbb{E}[F(\theta; \xi)] \}, \tag{7}
\]
where $D_\theta \subset \mathbb{R}^n$ is a nonempty convex compact set, $\xi$ is a random vector whose probability distribution $\mu$ is supported on $\Xi \subset \mathbb{R}^d$ and $F : D_\theta \times \Xi \rightarrow \mathbb{R}$. We assume that the expectation $\mathbb{E}[F(\theta; \xi)] = \int_\Xi F(\theta; \xi) d\mu(\xi)$ is well defined and finite-valued for every $\theta \in D_\theta$.

**Definition 1 (Proximal Operator).** Let $T$ be defined on a closed convex $\mathcal{X}$, and $\alpha > 0$. The proximal operator of $T$ is
\[
\mathcal{M}_{\alpha,T}(z) = \arg \min_{x \in \mathcal{X}} \left\{ T(x) + \frac{1}{\alpha} D_\psi(x,z) \right\}, \tag{8}
\]
where $\psi(\cdot)$ is a continuously differentiable, $\zeta$-strictly convex function satisfying $(x - y, \nabla \psi(x) - \nabla \psi(y)) \geq \zeta ||x - y||^2$, $\zeta > 0$, $D_\psi(\cdot, \cdot)$ is Bregman distance: $\forall x, y \in \mathcal{X}$,
\[
D_\psi(x,y) = \psi(x) - \psi(y) - \langle \nabla \psi(y), x - y \rangle.
\]

**Stochastic Mirror Descent (SMD).** The SMD solves (7) by generating an iterative solution as follows,
\[
\theta_{t+1} = \mathcal{M}_{\alpha_t,T}(\theta_t) = \arg \min_{\theta \in D_\theta} \left\{ \langle g_t, \theta \rangle + \frac{1}{\alpha_t} D_\psi(\theta, \theta_t) \right\}, \tag{9}
\]
where $\alpha_t > 0$ is step-size, $\ell(\theta) = \langle g_t, \theta \rangle$ is the first-order approximation of $f(\theta)$ at $\theta_t$, $g_t = g(\theta_t, \xi_t)$ is stochastic subgradient such that $g(\theta_t, \xi_t) \in \partial \ell(\theta) \in \mathbb{R}^d$, $\xi_t \geq 0$ represents a draws form distribution $\mu$, and $\ell(\theta) = \langle g(\theta) - f(\omega) \leq \gamma \ell(\theta - \omega), \forall \omega \in \text{dom}(f) \rangle$. If we choose $\psi(x) = \frac{1}{2} ||x||_2^2$, then $D_\psi(x,y) = \frac{1}{2} ||x - y||_2^2$, since then iteration (9) is reduced to stochastic gradient descent (SGD).

**Convergence Criteria: Bregman Gradient.** Recall $\mathcal{X}$ is a closed convex set on $\mathbb{R}^n$, $\alpha > 0$, $T(x)$ is defined on $\mathcal{X}$. The Bregman gradient of $T$ at $x \in \mathcal{X}$ is defined as:
\[
G_{\alpha,T}(x) = -1(x - \mathcal{M}_{\alpha,T}(x)), \tag{10}
\]
where $\mathcal{M}_{\alpha,T}(\cdot)$ is defined in Eq.(8). If $\psi(x) = \frac{1}{2} ||x||_2^2$, according to Bauschke, Combettes et al. (2011, Theorem 27.1), then $x^*$ is a critical point of $T$ if and only if $G_{\alpha,T}(x^*) = \nabla T(x^*) = 0$. Thus, Bregman gradient (10) is a generalization of standard gradient. Remark 1 provides us some insights to understand Bregman gradient as a convergence criterion.

**Remark 1.** Let $T(\cdot)$ be a convex function, according to Bertsekas (2009, Proposition 5.4.7): $x^*$ is a stationarity point of $T(\cdot)$ if and only if
\[
0 \in \partial(T + \delta_\chi(x^*)^{\infty}), \tag{11}
\]
where $\delta_\chi(\cdot)$ is the indicator function on $\mathcal{X}$. Furthermore, if $\psi(x)$ is twice continuously differentiable, let $\tilde{x} = \mathcal{M}_{\alpha,T}(x)$, by the definition of $\mathcal{M}_{\alpha,T}(\cdot)$ (8), we have
\[
0 \in \partial(T + \delta_\chi(\tilde{x})) + \langle \nabla \psi(\tilde{x}) - \nabla \psi(x) \rangle \Rightarrow \partial(T + \delta_\chi(\tilde{x})) + \alpha G_{\alpha,T}(x) \nabla \psi(x), \tag{12}
\]
Eq.(*) holds due to Taylor expansion of $\nabla \psi(x)$ on first order. If $G_{\alpha,T}(x) \approx 0$, Eq.(12) implies the origin point 0 is near the set $\partial(T + \delta_\chi(\tilde{x}))$, i.e., according to the criteria (11), $\tilde{x}$ is close to a stationary point. For the iteration (9), we focus on the time when it makes the $G_{\alpha,T}(\theta_i)$ near origin point 0. Formally, we are satisfied with finding an $\epsilon$-approximate first-order stationary point ($\epsilon$-FOSP) $\theta$, such that
\[
||G_{\alpha,T}(\theta) \epsilon \leq \epsilon. \tag{13}
\]
Particularly, for policy optimization (2), we would choose $T(\theta) = -\langle \nabla J(\theta), \theta \rangle$.

**Stochastic Mirror Policy Optimization**

In this section, we solve the problem (2) via SMD. Firstly, we analyze the theoretical dilemma of applying SMD directly to policy optimization, and result shows that under the common Assumption 1, there still lacks a provable guarantee of solving (2) via SMD directly. Then, we propose a convergent mirror policy optimization algorithm (MPO).
Theoretical Dilemma
For each $k \in [1, N-1]$, $\tau_k = \{s_t, a_t, r_{t+1}\}_{t=0}^{H_{\tau_k}} \sim \pi_{\theta_k}$, and we receive the gradient information as follows,
\[ -g(\tau_k | \theta_k) = - \sum_{t \geq 0} \nabla_{\theta} \log \pi_{\theta}(a_t | s_t) R(\tau_k) |_{\theta = \theta_k}. \quad (14) \]

According to (9), we define the update rule as follows,
\[
\theta_{k+1} = \mathcal{M}^\psi_{\alpha_k, (-g(\tau_k | \theta_k), \theta)}(\theta_k) \\
= \arg \min_\theta \left\{ \langle -g(\tau_k | \theta_k), \theta \rangle + \frac{1}{\alpha_k} D_\psi(\theta, \theta_k) \right\},
\]
where $\alpha_k$ is step-size. After $(N-1)$ episodes, we receive a collection $\{\theta_k\}_{k=1}^N$. Since $-J(\theta)$ is non-convex, according to Ghadimi, et al (2016), a standard strategy for analyzing non-convex optimization is to pick up the output $\hat{\theta}_N$ from the following distribution (16) over $\{1, 2, \ldots, N\}$:
\[
P(\hat{\theta}_N = \theta_k) = \frac{\zeta \alpha_k - \lambda \alpha_k^2}{\sum_{i=1}^N (\zeta \alpha_i - \lambda \alpha_i^2)}, k \in [1, N], \quad (16)
\]
where step-size $\alpha_k \in (0, \zeta/L)$.

**Theorem 1.** (Ghadimi, et al (2016)) Under Assumption 1, consider the sequence $\{\theta_k\}_{k=1}^N$ generated by (15), the output $\hat{\theta}_N = \theta_k$ follows the distribution (16). Let $\ell(g, u) = \langle g, u \rangle$, $g_k = \ell(\tau_k | \theta_k)$. Let $\Delta = J(\theta^*) - J(\theta_1)$.

Then,
\[
\begin{align*}
\mathbb{E}[[G_{\alpha_k, \ell(-g_k, \theta_k)}(\hat{\theta}_N)]]^2 &\leq \frac{\Delta + \sigma^2/\zeta \sum_{i=1}^N \alpha_i}{\sum_{i=1}^N (\zeta \alpha_i - \lambda \alpha_i^2)}, \quad (17)
\end{align*}
\]

Unfortunately, the lower bound of (17) reaches
\[
\frac{J(\theta^*) - J(\theta_1) + \sigma^2/\zeta \sum_{i=1}^N \alpha_i}{\sum_{i=1}^N (\zeta \alpha_i - \lambda \alpha_i^2)} \geq \frac{\sigma^2}{\zeta^2}, \quad (18)
\]
which cannot guarantee the convergence of (15), no matter how the step-size $\alpha_k$ is specified. Thus, under Assumption 1, updating parameters according to (15) and the output following (16) lacks a provable convergence guarantee.

**Discussion 1 (Open Problems).** Eq.(15) is a general rule that unifies many existing algorithms. If $\psi(\theta) = \frac{1}{2} \| \theta \|^2_2$, then (15) is VPG (Williams 1992). The update (15) is natural policy gradient (Kakade 2002) if we choose $\psi(\theta) = \frac{1}{2} \theta^T F(\theta) \theta$, where $F(\theta) = \mathbb{E}_{\pi^\theta}[\nabla_\theta \log \pi^\theta(s, a) \nabla_\theta \log \pi^\theta(s, a)^T]$ is Fisher information matrix. If $\psi$ is Boltzmann-Shannon entropy, then $D_\psi$ is KL divergence and update (15) is reduced to relative entropy policy search (Peters et al. 2010). Despite extensive works around these methods, existing works are scattered and fragmented in both theoretical and empirical aspects (Agarwal et al. 2020). Thus, it is of great significance to establish the fundamental theoretical convergence properties of iteration (15):

**What conditions guarantee the convergence of (15)?**
This is an open problem. From the previous discussion, intuitively, the iteration (15) is a convergent scheme since particular mirror maps $\psi$ can lead (15) to some popular empirically effective policy-based RL algorithms, but there still lacks a complete theoretical convergence analysis of (15).

---

**Algorithm 1:** MPO

```
1: Initialize: parameter $\theta_1$, step-size $\alpha_k > 0$, $g_0 = 0$, parameter policy $\pi^\theta(a|s)$, and map $\psi$.
2: for $k = 1$ to $N$ do
3: Generate a trajectory $\tau_k = \{s_t, a_t, r_{t+1}\}_{t=0}^{H_{\tau_k}} \sim \pi_{\theta_k}$, temporary variable $g_0 = 0$.
4: $g_k \leftarrow \sum_{t=0}^{H_{\tau_k}} \nabla_{\theta} \log \pi_{\theta}(a_t | s_t) R(\tau_k) |_{\theta = \theta_k}$
5: $\hat{\theta}_k \leftarrow \frac{1}{k} \sum_{i=1}^k g_i + (1 - \frac{1}{k}) \hat{g}_{k-1}$
6: end for
7: Output $\hat{\theta}_N$ according to (16).
```

**MPO: A Convergent Implementation**
In this section, we propose a convergent mirror policy optimization (MPO) as follows, for each step $k$:
\[
\theta_{k+1} = \mathcal{M}^\psi_{\alpha_k, (-g_k, \theta_k)}(\theta_k) \\
= \arg \min_\theta \left\{ \langle -g_k, \theta \rangle + \frac{1}{\alpha_k} D_\psi(\theta, \theta_k) \right\},
\]
where $\hat{g}_k$ is an arithmetic mean of previous episodes’ gradient estimate $\{g(\tau_i | \theta_k)\}_{i=1}^k$:
\[
\hat{g}_k = \frac{1}{k} \sum_{i=1}^k g(\tau_i | \theta_k).
\]

We present the details of an implementation of MPO in Algorithm 1. Eq.(22) is an incremental implementation of the average (20), thus, (22) enjoys a lower storage cost than (20).

For a given episode, the gradient flow (20)/(22) of MPO is slightly different from the traditional VPG, REINFORCE (Williams 1992), or DPG (Silver et al. 2014) whose gradient estimator (14) follows the current episode, while our MPO uses an arithmetic mean of all the previous policy gradients.

The gradient estimator (14) is a natural way to estimate the term $- \nabla J(\theta_k) = - \mathbb{E}_{\sum_{i=0}^{H_{\tau_k}} \nabla_\theta \log \pi_{\theta_k}(a_k | s_k) R(\tau_k)}$, i.e., using the current trajectory to estimate policy gradient.

**Theorem 2 (Convergence of Algorithm 1).** Under Assumption 1, and the total trajectories are $\{\tau_k\}_{k=1}^N$. Consider the sequence $\{\theta_k\}_{k=1}^N$ generated by Algorithm 1, and the output $\hat{\theta}_N = \theta_k$ follows the distribution of (16). Let $0 < \alpha_k < \frac{1}{L}$, $\ell(g, u) = \langle g, u \rangle$, $\hat{g}_k = \frac{1}{k} \sum_{i=1}^k g_i$, and $\Delta = J(\theta^*) - J(\theta_1)$.

where $g_i = \sum_{t=0}^{H_{\tau_k}} \nabla_\theta \log \pi_{\theta_k}(a_k | s_k) R(\tau_k) |_{\theta = \theta_k}$. Then the output $\hat{\theta}_N = \theta_k$ satisfies
\[
\mathbb{E}[[G_{\alpha_k, \ell(-g_k, \theta_k)}(\theta_k)]]^2 \leq \frac{\Delta + \sigma^2/\zeta \sum_{i=1}^N \alpha_i}{\sum_{i=1}^N (\zeta \alpha_i - \lambda \alpha_i^2)},
\]
\[
\frac{\Delta + \sigma^2/\zeta \sum_{i=1}^N \alpha_i}{\sum_{i=1}^N (\zeta \alpha_i - \lambda \alpha_i^2)} \leq \Omega \left( \frac{\ln N}{N} \right).
\]
VRMPO: Variance Reduction Mirror Policy Optimization

In this section, we propose a variance reduction version of MP0: VRMPO. Inspired by the above work of (Nguyen et al. 2017a), we provide an efficiently computable policy gradient estimator; then, we prove that the VRMPO needs $O(\epsilon^{-3})$ sample trajectories to achieve an $\epsilon$-FOSP that matches the best sample complexity.

Methodology. For any initial $\theta_0$, let $\{\tau_j^0\}_{j=1}^N \sim \pi_{\theta_0}$, we estimate the initial policy gradient as follows,

$$G_0 = -\nabla_N J(\theta_0) = -\frac{1}{N} \sum_{j=1}^N g(\tau_j^0|\theta_0). \quad (25)$$

Let $\theta_j = \theta_0 - \alpha G_0$, for each step $k \in \mathbb{N}^+$, let $\{\tau_j^k\}_{j=1}^N$ be the trajectories generated by $\pi_{\theta_k}$, we define the policy gradient estimator $G_k$ and update rule as follows,

$$G_k = G_{k-1} + \frac{1}{N} \sum_{j=1}^N \left( -g(\tau_j^k|\theta_k) + g(\tau_j^k|\theta_{k-1}) \right), \quad (26)$$

$$\theta_{k+1} = \arg \min_{\theta} \{G_k(\theta) + \frac{1}{\alpha} D_\psi(\theta, \theta_k)\}. \quad (27)$$

In (26), $-g(\tau_j^k|\theta_k)$ and $g(\tau_j^k|\theta_{k-1})$ share the same trajectory $\{\tau_j^k\}_{j=1}^N$, which plays a critical role in reducing the variance of gradient estimator (Shen et al. 2019). Besides, it is different from (20), we admit a simple recursive formulation to conduct the gradient estimator, see (26), which captures the technique from SARAH (Nguyen et al. 2017a). For each step $k$, the term $\frac{1}{N} \sum_{j=1}^N \left( -g(\tau_j^k|\theta_k) + g(\tau_j^k|\theta_{k-1}) \right)$ can be seen as an additional “noise” for the policy gradient estimate. A lot of practices show that conducting a gradient estimator with such additional “noise” enjoys a lower variance and speeding up the convergence (Reddi et al. 2016). More details are shown in Algorithm 2.

Theorem 3 (Convergence Analysis). Consider $\{\theta_k\}_{k=1}^K$ generated by Algorithm 2. Under Assumption 1, and let $\zeta > \frac{3}{32}$. For any positive scalar $\epsilon$, let batch size of the trajectories of the outer loop $N_1 = \left( \frac{8L}{2\zeta^2} + \frac{1}{2\zeta^2} \right) \frac{1}{\epsilon^2}$, the outer loop times $K = \left( \frac{8L}{2\zeta^2} + \frac{1}{2\zeta^2} \right) \frac{1}{\epsilon^2}$, and step size $\alpha = \frac{1}{4\epsilon}$. Then, Algorithm 2 outputs $\theta_K$ satisfies

$$\mathbb{E}[\|G^\psi_{\alpha, (-\nabla J(\theta_K), \theta)}(\theta_K)\|] \leq \epsilon. \quad (30)$$

For its proof, see Appendix C. Theorem 2 illustrates that VRMPO needs $K(N_1 + (m-1)N_2) = \frac{8L(1+\zeta^2)}{\zeta^2} \frac{1}{\epsilon^2} \left( 1 + \frac{1}{8L(1+\zeta^2)} \right)$ random trajectories to achieve the $\epsilon$-FOSP. As far as we know, our VRMPO matches the best sample complexity as HAPG (Shen et al. 2019) and SRVR-PG (Xu et al. 2020; Xu 2021). In fact, according to Shen et al. (2019), REINFORCE needs $O(\epsilon^{-4})$ random trajectories to achieve the $\epsilon$-FOSP and no provable improvement on its complexity has been made so far. The same order of sample complexity of REINFORCE is shown by Xu et al. (2019). With the additional assumptions $\text{Var}[\nabla J(\theta)] < \infty$, Papini et al. (2018) show that the SVRPG achieves the sample complexity of $O(\epsilon^{-3})$. Later, under the same assumption as Papini et al. (2018), Xu et al. (2019) reduce the sample complexity of SVRPG to $O(\epsilon^{-\frac{5}{2}})$. We summarize it in Table 1.

Remark 2. It’s remarkable that although our VRMPO shares sample complexity with HAPG, SRVR-PG, and VR-BGPO(Huang et al. 2021), the difference between our VRMPO and theirs are at least three aspects: Firstly, Shen et al. (2019) derive their HAPG from the information of Hessian policy, our VRMPO provides a simple recursive formulation to conduct the gradient estimator. Secondly, if the mirror map $\psi$ is reduced to the $\ell_2$-norm, then VRMPO is SRVR-PG exactly, i.e., VRMPO unifies SRVR-PG. From Table 1, we see VRMPO needs less conditions than Xu et al. (2020) to achieve the same sample complexity. Finally, Shen et al. (2019), Xu et al. (2020) and Huang et al. (2021) only provide an off-line (i.e., Monte Carlo) policy gradient estimator, which is limited in complex domains. We have provided an on-line version of VRMPO, and discuss some insights of practical tracks to the application to the complex domains, please see the section of experiment on MuJoCo task, Appendix E.1.

Related Works

Stochastic Variance Reduced Gradient in RL. To our best knowledge, Du et al. (2017) firstly introduce SVRG (Johnson and Zhang 2013) to off-policy evaluation (Yang et al. 2018).
Du et al. (2017) transform the empirical policy evaluation problem into a convex-concave saddle-point problem, then they solve the problem via SVRG straightforwardly. Later, to improve sample efficiency for complex RL, Xu et al. (2020; Xu, 2021) combine SVRG with TRPO (Schulman et al. 2015). Similarly, Yuan et al. (2019) introduce SARAH (Nguyen et al. 2017a) to TRPO to improve sample efficiency. However, the results presented by Xu et al. (2017) and Yuan et al. (2019) are empirical, which lacks a strong theory analysis. Metelli et al. (2018) present a surrogate objective function with Rényi divergence (Rényi et al. 1961) to reduce the variance. Recently, Papini et al. (2018) propose a stochastic variance reduced version of policy gradient (SVRG), and they define the gradient estimator via importance sampling:

\[
\hat{G}_{k-1} + \frac{1}{N} \sum_{j=1}^{N} \left( -g(\tau_{j}^{k} | \theta_{t}) + \prod_{i=0}^{H} \frac{\pi_{\theta_{i}}(a_{i} | s_{i})}{\pi_{\hat{\theta}_{i}}(a_{i} | s_{i})} g(\tau_{j}^{k} | \theta_{t-1}) \right),
\]

where \( \hat{G}_{k-1} \) is an unbiased estimator according to the trajectory generated by \( \pi_{\hat{\theta}_{k-1}} \). Although SVRG is practical empirically, its gradient estimate is dependent heavily on importance sampling. This fact partially reduces the effectiveness of variance reduction. Later, Shen et al. (2019) remove the importance sampling term, and they construct a Hessian aided policy gradient. Our VRMPO is different from Du et al. (2017); Xu, et al. (2017); Papini et al. (2018), which admits a stochastic recursive iteration to estimate the policy gradient. VRMPO exploits fresh information to improve convergence and reduces variance. Besides, VRMPO reduces the storage cost since it doesn’t require to store the complete historical information.

Baseline Methods. Baseline (also also known as control variates) is a widely used technique to reduce the variance (Weaver and Tao 2001; Greensmith et al. 2004). For example, A2C (Sutton and Barto 1998; Mnih et al. 2016) introduces the value function as baseline function, Wu et al. (2018) consider action-dependent baseline, and Liu et al. (2018) use the Stein’s identity (Stein 1986) as baseline. Q-Prop (Gu et al. 2017) makes use of both the linear dependent baseline and GAE (Schulman et al. 2016) to reduce variance. Cheng et al. (2019) present a predictor-corrector framework transforms a first-order model-free algorithm into a new hybrid method that leverages predictive models to accelerate policy learning. Mao et al. (2019) derive a bias-free, input-dependent baseline to reduce variance, and analytically show its benefits over state-dependent baselines. Recently, Grathwohl et al. (2018); Cheng, et al. (2019) provide a standard explanation for the benefits of such approaches with baseline function. However, the capacity of all the above methods is limited by their choice of baseline function (Liu et al. 2018). In practice, it is troublesome to design a proper baseline function to reduce the variance of policy gradient estimate. Our VRMPO avoids the selection of baseline function, and it uses the current trajectories to construct a novel, efficiently computable gradient to reduce variance and improve sample efficiency.

Experiments

Our experiments cover the following three different aspects:

• We provide a numerical analysis of MPO, and compare the convergence rate of MPO with REINFORCE and VPG on the Short Corridor with Switched Actions (SASC) domain (Sutton and Barto 2018).

• We provide a better understand the effect of how the mirror map affects the performance of VRMPO.

• To demonstrate the stability and efficiency of VRMPO on the MuJoCo continuous control tasks, we provide a comprehensive comparison to state-of-the-art policy optimization algorithms.
Numerical Analysis of MPO
SASC Domain (see Appendix B): The task is to estimate the optimal value function of state \( s_1 \), \( V(s_1) = G_0 \approx -11.6 \). Let \( \phi(s, \text{right}) = [1, 0] \) and \( \phi(s, \text{left}) = [0, 1] \), \( s \in \mathcal{S} \). Let \( L_0(s, a) = \phi^\top(s, a)\theta_0, (s, a) \in \mathcal{S} \times \mathcal{A} \), where \( \mathcal{A} = \{\text{right, left}\} \). \( \pi_\theta(a|s) \) is the soft-max distribution defined as \( \pi_\theta(a|s) = \exp(L_0(s, a)) / \sum_{a' \in \mathcal{A}} \exp(L_0(s, a')) \). The initial parameter \( \theta_0 \sim \mathcal{U}[-0.5, 0.5] \), where \( \mathcal{U} \) is the uniform distribution.

Before we report the results, it is necessary to explain why we only compare MPO with VRP and VPG. VPG/REINFORCE is one of the most fundamental policy gradient methods in RL, and extensive modern policy-based algorithms are derived from VPG/REINFORCE. Our MPO is a new policy gradient algorithm to learn the parameter. Thus, it is natural to compare with VPG and REINFORCE. The result of Figure 1 shows that MPO converges faster significantly than both REINFORCE and VPG.

Effect of Mirror Map on VRMPO
If \( \psi(\cdot) \) is \( \ell_p \)-norm, then \( \psi^*(y) = (\sum_{i=1}^n |y_i|^q)^{1/q} \) is the conjugate map of \( \psi \), where \( y = (y_1, y_2, \cdots, y_n)^\top \), \( \frac{1}{p} + \frac{1}{q} = 1 \), and \( p, q > 1 \). According to Beck and Teboulle (2003), iteration (27) is equivalent to

\[ \theta_{k+1} = \nabla \psi^*(\nabla \psi(\theta_k) + \alpha G_k), \]

where \( \nabla \psi_j(x) = \frac{\text{sign}(x_j)|x_j|^{p-1}}{||x||_p^{p-1}}, \nabla \psi^*_j(y) = \frac{\text{sign}(y_j)|y_j|^{q-1}}{||y||_q^{q-1}} \), and \( j \) is coordinate index of the vector \( \nabla \psi, \nabla \psi^* \).

To compare fairly, we use the same random seed for each domain. The hyper-parameter \( p \) runs in the set \( P = \{1.1, 1.2, \cdots, 1.9, 2, 3, 4, 5\} \). For the non-Euclidean distance case, we only show the results of \( p = 3, 4, 5 \) in Figure 2, and “best” is a certain hyper-parameter \( p \in \{P\} \) achieves the best performance among the set \( \{P\} \). We use a two-layer feedforward neural network of 200 and 100 hidden nodes, respectively, with rectified linear units (ReLU) activation function between each layer. We run the discountor \( \gamma = 0.99 \) and the step-size \( \alpha \) is chosen by a grid search from the set \( \{0.01, 0.02, 0.04, 0.08, 0.1\} \).

The result of Figure 2 shows that the best method is produced by non-Euclidean distance \( (p \neq 2) \), not the Euclidean distance \( (p = 2) \). The traditional policy gradient methods such as REINFORCE, VPG, and DPG are all the algorithms update parameters by Euclidean distance. This experiment gives us some light that one can create better algorithms with existing approaches via non-Euclidean distance. Additionally, the result of Figure 2 shows our VRMPO converges faster than REINFORCE, i.e., VRMPO needs less sampled trajectories to reach a convergent state, which supports the complexity analysis in Table 1. Although SRVR-PG achieves the same sample complexity as our VRMPO, result of Figure 2 shows VRMPO converges faster than SRVR-PG.

Evaluate VRMPO on Continuous Control Tasks
It is noteworthy that the policy gradient (26) of VRMPO is an off-line estimator likes REINFORCE. As pointed by Sutton and Barto (2018), REINFORCE converge asymptotically to a local minimum, but like all off-line methods, it is inconvenient forcontinuous control tasks, and it is limited in the application to some complex domains. This could also happen in VRMPO.

Now, we introduce some practical tricks for on-line implementation of VRMPO. We have provided the complete update rule of on-line VRMPO in Algorithm 3.

Details of Implementation. Firstly, we extend Algorithm 2 to be an actor-critic structure, i.e., we introduce a critic structure to Algorithm 2. Concretely, for each step \( t \), we construct a critic network \( Q_\omega(s, a) \) with the parameter \( \omega \), sample \( \{(s_i, a_i)\}_{i=1}^N \) from a data memory \( \mathcal{D} \), and learn the parameter \( \omega \) via minimizing the critic loss as follows,

\[ L_\omega = \frac{1}{N} \sum_{i=1}^N \left[ r_{i+1} + \gamma Q_{\omega_{k-1}}(s_i, a_i) - Q_\omega(s_i, a_i) \right]^2. \]  

(31)

For more details, please see Line 17-20 of Algorithm 3. Then, for each pair \( (s, a) \sim \mathcal{D} \), we conduct the actor loss \( L_\theta(s, a) = -\log \pi_\theta(s, a) Q_{\omega_{k-1}}(s, a) \) to replace \( J(\theta) \) to learn parameter \( \theta \). For more details, please see Line 9-16 of Algorithm 3 (Appendix E.1).

Score Performance Comparison. From the results of Figure 3 and Table 2, overall, VRMPO outperforms the baseline algorithms in both final performance and learning process. Our VRMPO also learns considerably faster with better
performance than the popular TD3 on Walker2d, HalfCheetah, Hopper, InvDoublePendulum (IDP), and Reacher domains. On the InvDoublePendulum task, our VRMPO has only a small advantage over other algorithms. The InvPendulum task is relatively easy, the advantage of our VRMPO becomes more powerful when the task is more difficult. It is worth noticing that on the HalfCheetah domain, our VRMPO achieves a significant max-average score 16000+, which outperforms far more than the second-best score 11781.

### Stability

The stability of an algorithm is also an important topic in RL. Although DDPG exploits the off-policy samples, which promotes its efficiency in stable environments. DDPG is unstable on the Reacher task, while our VRMPO learning faster significantly with lower variance. DDPG fails to make any progress on InvDoublePendulum domain, which is corroborated by (Dai et al. 2018). Although TD3 takes the minimum value between a pair of critics to limit overestimation, it learns severely fluctuating in the InvertedDoublePendulum environment. In contrast, our VRMPO is consistently reliable and effective in different tasks.

### Variance Comparison

As we can see from the results in Figure 3, our VRMPO converges with a considerably low variance in the Hopper, InvDoublePendulum, and Reacher. Although the asymptotic variance of VRMPO is slightly larger than other algorithms in HalfCheetah, the final performance of VRMPO outperforms all the baselines significantly. The result of Figure 3 also implies conducting a proper gradient estimator not only reduces the variance of the score during the learning but speeds the convergence of training.

### Conclusion

In this paper, we analyze the theoretical dilemma of applying SMD to policy optimization. Then, we propose a sample efficient algorithm VRMPO, and prove the sample complexity of VRMPO achieves only $O(\epsilon^{-3})$. To our best knowledge, VRMPO matches the best sample complexity so far. Finally, we conduct extensive experiments to show our algorithm outperforms state-of-the-art policy gradient methods.
