Abstract

We study risk-sensitive reinforcement learning (RL) based on an entropic risk measure in episodic non-stationary Markov decision processes (MDPs). Both the reward functions and the state transition kernels are unknown and allowed to vary arbitrarily over time with a budget on their cumulative variations. When this variation budget is known a priori, we propose two restart-based algorithms, namely Restart-RSMB and Restart-RSQ, and establish their dynamic regrets. Based on these results, we further present a meta-algorithm that does not require any prior knowledge of the variation budget and can adaptively detect the non-stationarity on the exponential value functions. A dynamic regret lower bound is then established for non-stationary risk-sensitive RL to certify the near-optimality of the proposed algorithms. Our results also show that the risk control and the handling of the non-stationarity can be separately designed in the algorithm if the variation budget is known a prior, while the non-stationary detection mechanism in the adaptive algorithm depends on the risk parameter. This work offers the first non-asymptotic theoretical analyses for the non-stationary risk-sensitive RL in the literature.

1 Introduction

Risk-sensitive RL considers problems in which the objective takes into account risks that arise during the learning process, in contrast to the typical expected accumulated reward objective. Effective management of the variability of the return in RL is essential in various applications in finance (Markowitz 1968), autonomous driving (Garcia and Fernández 2015) and human behavior modeling (Niv et al. 2012).

While classical risk-sensitive RL assumes that an agent interacts with a time-invariant (stationary) environment, both the reward functions and the transition kernels can be time-varying for many risk-sensitive applications. For example, in finance (Markowitz 1968), the federal reserve adjusts the interest rate or the balance sheet in a non-stationary way and the market participants should adjust their trading policies accordingly. In the medical treatments (Man et al. 2014), the patient’s health condition and the sensitivity of the patient’s internal body organs to the medicine vary over time. This non-stationarity should be accounted for to minimize the risk of any potential side effects of the treatment. A similar requirement holds for the power grid control (Ding, Lavaei, and Arcak 2021) where the power grid contingency needs to be prepared with the time-varying electricity loads.

Despite the importance and ubiquity of non-stationary risk-sensitive RL problems, the literature lacks provably efficient algorithms and theoretical results. In this work, we study risk-sensitive RL with an entropic risk measure (Howard and Matheson 1972) under episodic Markov decision processes with unknown and time-varying reward functions and state transition kernels.

The non-stationary RL problem with an entropic risk measure has the following technical challenges. (1) Due to the non-stationarity of the model, any estimation error of the expectation operator may be tremendously amplified in the value function when the risk parameter $\beta$ is small. (2) In addition, the exponential Bellman equation (see Equation (3)) used in our risk-sensitive analysis associates the instantaneous reward and value function of the next step in a multiplicative way (Fei et al. 2021). However, this multiplicative feature of the exponential Bellman equation will also involve the policy evaluation errors due to the non-stationary drifting as multiplicative terms, which makes it more difficult to gauge the bounds than the risk-neutral non-stationary setting in which all policy evaluation errors are in an additive way. (3) Furthermore, the non-linearity of the objective function (see Equation (1)) makes it difficult to obtain an unbiased estimation of the value function, which is needed in the design of a non-stationary detection mechanism in risk-neutral non-stationary RL (Wei and Luo 2021). (4) It is unclear whether the risk control and the handling of the non-stationarity can be separately designed when achieving the optimal dynamic regret. To address these difficulties, we develop a novel analysis to carefully quantify the effect of the non-stationarity in risk-sensitive RL. Our main theoretical contributions, summarized in Table 1, are as follows

- When the variation budget is known a prior, we propose two provably efficient restart algorithms, namely Restart-RSMB and Restart-RSQ, and establish their dynamic regrets. The stationary version of the model-based method Restart-RSMB is also the first model-based risk-sensitive algorithm in the stationary setting in the literature.
- When the variation budget is unknown (parameter-free), we propose a meta-algorithm that adaptively detects the non-stationarity of the exponential value functions.

proposed adaptive algorithms, namely Adaptive-RSMB and Adaptive-RSQ, can achieve the (almost) same dynamic regret as the algorithms requiring the knowledge of the variation budget.

- We establish a lower bound result for non-stationary RL with entropic risk measure that certifies the near-optimality of our upper bounds.
- Our results also show that the risk control and the handling of the non-stationarity can be separately designed if the variation budget is known a prior, while the non-stationary detection mechanism in the adaptive algorithms depends on the risk parameter.

1.1 Related Work

**Non-stationary RL.** Non-stationary RL has been mostly studied in the risk-neutral setting. When the variation budget is known a prior, a common strategy for adapting to the non-stationarity is to follow the forgetting principle, such as the restart strategy (Mao et al. 2020; Zhou et al. 2020; Zhao et al. 2020; Ding and Lavaei 2022), exponential decayed weights (Touati and Vincent 2020), or sliding window (Cheung, Simchi-Levi, and Zhu 2020; Zhong, Yang, and Szepesvári 2021). In this work, we focus on the restart method mainly due to its advantage of the simplicity of the memory efficiency (Zhao et al. 2020) and generalize it to the risk-sensitive RL setting. However, the prior knowledge of the variation budget is often unavailable in practice. The work (Cheung, Simchi-Levi, and Zhu 2020) develop a Bandit-over-Reinforcement-Learning framework to relax this assumption, but it leads to the suboptimal regret. To achieve a nearly-optimal regret without the prior knowledge of the variation budget, (Auer, Gajane, and Ortner 2019) and (Chen et al. 2019) maintain a distribution over bandit arms with properly controlled variance for all reward estimators. For RL problems, the seminar work (Wei and Luo 2021) proposes a black-box reduction approach that turns a certain RL algorithm with optimal regret in a (near-)stationary environment into another algorithm with optimal dynamic regret in a non-stationary environment. However, the above works only consider risk-neutral RL and may not apply to the more general risk-sensitive RL problems.

**Risk-sensitive RL.** Many risk-sensitive objectives have been investigated in the literature and applied to RL, such as the entropic risk measure, Markowitz mean-variance model, Value-at-Risk (VaR), and Conditional Value at Risk (CVaR) (Moody and Saffell 2001; Chow and Ghavamzadeh 2014; Delage and Mannor 2010; La and Ghavamzadeh 2013; Di Castro, Tamar, and Mannor 2012; Tamar, Glassner, and Mannor 2015; Tamar et al. 2015; Howard and Matheson 1972). Our work is closely related to the entropic risk measure. Following the seminal paper (Howard and Matheson 1972), this line of work includes (Bäuerle and Rieder 2014; Borkar 2001; Borkar and Meyn 2002; Borkar 2002; Cavazos-Cadena and Fernández-Gaucherand 2000; Coraluppi and Marcus 1999; Di Masi and Stettner 1999; Fernández-Gaucherand and Marcus 1997; Fleming and McEneaney 1995; Hermández-Hernández and Marcus 1996; Osogami 2012; Fleming and McEneaney 1992; Shen, Stannat, and Obermayer 2013; Fei et al. 2020; Fei, Yang, and Wang 2021; Fei et al. 2021). In particular, when transitions are unknown and simulators of the environment are unavailable, the first non-asymptotic regret guarantees are established under the tabular setting in (Fei et al. 2020) and the function approximation setting in (Fei, Yang, and Wang 2021). Then, a simple transformation of the risk-sensitive Bellman equations is proposed in (Fei et al. 2021), which leads to improved regret upper bounds. However, the above papers all assume that the environment is stationary, and therefore their results may quickly collapse in a non-stationary environment.

2 Problem Formulation

2.1 Notations

For a positive integer $n$, let $[n] := \{1, 2, \ldots, n\}$. Given a variable $x$, the notation $a = \mathcal{O}(b(x))$ means that $a \leq C \cdot b(x)$ for some constant $C > 0$ that is independent of $x$. Similarly, $a = \tilde{\mathcal{O}}(b(x))$ indicates that the previous inequality may also depend on the function $\log(x)$, where $C > 0$ is again independent of $x$. In addition, the notation $a = \Omega(b(x))$ means that $a \geq C \cdot b(x)$ for some constant $C > 0$ that is independent of $x$.

2.2 Episodic MDP and Risk-Sensitive Objective

In this paper, we study risk-sensitive RL in non-stationary environments via episodic MDPs with adversarial bandit-information reward feedback and unknown adversarial transition dynamics. At each episode $m$, an episodic MDP is defined by the finite state space $\mathcal{S}$, the finite action space $\mathcal{A}$, a collection of transition probability measure $\{P_m(\cdot | \cdot)\}_{m \in \mathbb{N}}$ specifying the transition probability $P_m(s'|s, a)$ from state $s$ to the next state $s'$ under action $a \in \mathcal{A}$, a collection of reward functions $\{r'_m(s' | s)\}_{m \in \mathbb{N}}$, where $r'_m : \mathcal{S} \times \mathcal{A} \rightarrow [0, 1]$, and $H > 0$ as the length of episodes. In this paper, we focus on a bandit setting where the agent only observes the values of reward functions, i.e., $r_m(s, a)$ at the visited state-action pair $(s_m, a_m)$. We also assume that reward functions are deterministic to streamline the presentation, while our analysis readily generalizes to the setting where reward functions are random.

For simplicity, we assume the initial state $s_1$ to be fixed as $s_1$ in different episodes. We use the convention that the episode terminates when a state $s_{H+1}$ at step $H+1$ is reached, at which the agent does not take any further action and receives no reward.

A policy $\pi_m = \{\pi_h\}_{h \in [H]}$ of an agent is a sequence of functions $\pi_m : \mathcal{S} \rightarrow \mathcal{A}$, where $\pi_h(s)$ is the action that the agent takes in state $s$ at step $h$ at episode $m$. For each $h \in [H]$ and $m \in [M]$, we define the value function $V_{h, m}^\pi : \mathcal{S} \rightarrow \mathbb{R}$ of a policy $\pi$ as the expected value of the cumulative rewards the agent receives under a risk measure of exponential utility by executing $\pi$ starting from an arbitrary state at step $h$.

Specifically, we have

$$ V_{h, m}^\pi(s) := \frac{1}{\beta} \log \left\{ \mathbb{E}_{\pi, P_m} \left[ \exp \left( \beta \sum_{i=1}^{H} r'_i(s_i, a_i) \right) | s_h = s \right] \right\} \quad (1) $$

7406
where the expectation $\mathbb{E}_s, \pi, \rho''$ is taken over the random state-action sequence $\{(s^m, a^m)\}_{i=1}^H$, the action $a^m_i$ follows the policy $\pi_i^m \cdot a^m$, and the next state $x_{i+1}$ follows the transition dynamics $P^m \cdot a^m_i$. Here $\beta \neq 0$ is the risk parameter of the exponential utility. $\beta > 0$ corresponds to a risk-seeking value function, $\beta < 0$ corresponds to a risk-averse value function, and as $\beta \to 0$ the agent tends to be risk-neutral.

We further define the action-value function $Q^m_h : \mathcal{S} \times \mathcal{A} \to \mathbb{R}$, for each $h \in [H]$ and $m \in [M]$, which gives the expected value of the risk measured by the exponential utility when the agent starts from an arbitrary state-action pair and follows the policy $\pi$ afterwards; that is,

$$Q^m_h(s, a) = \mathbb{E}_s, \pi^m_h \left( \int_{i=1}^H \exp(\beta m_i(s_i, a_i)) \right)$$

for all $(s, a) \in \mathcal{S} \times \mathcal{A}$. Under some mild regularity conditions (Bäuerle and Rieder, 2014), for each episode $m$, there always exists an optimal policy, denoted as $\pi^m$, that yields the optimal value $V^m_h(s) = \sup_{\pi} V^m_h(s)$ for all $(h, s) \in [H] \times \mathcal{S}$. For convenience, we denote $V^m_h(s)$ as $V^m_h(s)$ when it is clear from the context.

### 2.3 Exponential Bellman Equation

For all $(s, a, h, m) \in \mathcal{S} \times \mathcal{A} \times [H] \times [M]$, the Bellman equation associated with $\pi$ is given by

$$Q^m_h(s, a) = r^m_h(s, a) + \frac{1}{\beta} \log \{ \mathbb{E}_{s', P^m_h(s, a)} \left[ e^{\beta V^m_{h+1}(s')} \right] \},$$

(2a)

$$V^m_h(s) = Q^m_h(s, \pi(s)).$$

(2b)

In Equation (2), it can be seen that the action value $Q^m_h$ of step $h$ is a non-linear function of the value function $V^m_{h+1}$ of the later step. Based on Equation (2), for $h \in [H]$ and $m \in [M]$, the Bellman optimality equation is given by

$$V^m_h(s) = \max_{a \in \mathcal{A}} Q^m_h(s, a), \quad V^m_h(s) = 0.$$

It has been recently shown in (Fei et al. 2021) that under the risk-sensitive measure, it is easier to analyze a simple transformation of the Bellman equation (by taking exponential on both sides of (2)), which is called exponential Bellman equation: for every policy $\pi$ and tuple $(s, a, h, m)$, we have

$$e^{\beta Q^m_h(s, a)} = \mathbb{E}_{s', P^m_h(s, a)} \left[ e^{\beta (V^m_{h+1}(s') + V^m_{h+1}(s'))} \right].$$

(3)

When $\pi = \pi^m$, we obtain the corresponding optimality equation

$$e^{\beta Q^m_h(s, a)} = \mathbb{E}_{s', P^m_h(s, a)} \left[ e^{\beta (V^m_{h+1}(s') + V^m_{h+1}(s'))} \right].$$

(4)

Note that Equation (3) associates the current and future cumulative utilities $(Q^m_h)$ and $(V^m_{h+1})$ in a multiplicative way, rather than in an additive way as in the standard Bellman equations (2).

### 2.4 Non-stationarity and Variation Budget

In this work, we focus on a non-stationary environment where the transition function $P^m_h$ and reward functions $r^m_h$ can vary over the episodes. We measure the non-stationarity of the MDP over an interval $I$ in terms of its variation in the reward functions and transition kernels:

$$B_{r, I} = \sum_{m \in I} \sup_{h=1}^H \left| r^m_h(s, a) - r^{m+1}_h(s, a) \right|,$$

$$B_{P, I} = \sum_{m \in I} \sup_{h=1}^H \left| P^m_h(s', \cdot | s, a) - P^{m+1}_h(s', \cdot | s, a) \right|.$$
Note that our definition of variation only imposes restrictions on the summation of non-stationarity across different episodes, and does not put any restriction on the difference between two steps in the same episode. We further let \( B_r := B_r[1,M] \), \( B_p := B_p[1,M] \), and \( B := B_r + B_p \), and assume \( B > 0 \).

### 2.5 Performance Metrics

Since both the reward and the transition dynamics vary over the episodes and are revealed only after a policy is decided, the agent aims to ensure the long-term optimality guarantee over some given period of episodes \( M \). Suppose that the agent executes policy \( \pi^m \) in episode \( m \). We now define the dynamic regret as the difference between the total reward value of policy \( \{\pi^m\}_{m=1}^M \) and that of the agent’s policy \( \pi^m \) over \( M \) episodes:

\[
\text{D-Regret}(M) := \sum_{m=1}^M (V^*_{1:m} - V_{\pi^m,1:m}).
\]

### 3 Restart Algorithms with The Knowledge of Variation Budget

#### 3.1 Periodically Restarted Risk-Sensitive Model-Based Method

We first present the Periodically Restarted Risk-sensitive Model-based method (Restart-RSMB) in Algorithm 1. It consists of two main stages: estimation of value function (line 7-13) with the periodical restart (line 5) and the policy evaluation (line 15).

To estimate the value function under the unknown non-stationarity, we take the optimistic value evaluation to properly handle the exploration-exploitation trade-off and apply the restart strategy to adapt to the unknown non-stationarity. In particular, we reset the visitation counters \( N_h^m(s,a) \) and \( N_h^m(x,a) \) to zero every \( W \) episodes (line 5). Then, the reward and transition dynamics are estimated using only the data from the episode \( m = \left\lfloor \frac{W}{m} \right\rfloor + 1 \) to the episode \( m \) by

\[
\bar{P}_h^m(s'|s,a) = \frac{N_h^m(s,a,s')}{N_h^m(s,a) + \lambda}, \quad (5a)
\]

for all \( (s,a,s') \in \mathcal{S} \times \mathcal{A} \times \mathcal{S} \),

\[
\bar{r}_h^m(s,a) = \sum_{s'} \bar{P}_h^m(s'|s,a) r_h^m(s', a), \quad (5b)
\]

for all \( (s,a) \in \mathcal{S} \times \mathcal{A} \),

which are used to compute the estimated cumulative rewards at step \( h \) (line 9). To encourage a sufficient exploration in the uncertain environment, Algorithm 1 applies the counter-based Upper Confidence Bound (UCB). Under the entropic risk measure, this bonus term takes the form

\[
\begin{align*}
C_1 \left( e^{\beta(H-h+1)} - 1 \right) + e^{\beta(H-h+1)} \beta \sqrt{\frac{\log(6WHS|\mathcal{A}|/p)}{N_h^m(s,a)+1}}, & \quad \text{if } \beta > 0, \\
C_1 \left( 1 - e^{\beta(H-h+1)} \right) - \beta \sqrt{\frac{\log(6WHS|\mathcal{A}|/p)}{N_h^m(s,a)+1}}, & \quad \text{if } \beta < 0,
\end{align*}
\]

(6)

Algorithm 1: Periodically Restarted Risk-sensitive Model-based RL (Restart-RSMB)

1: **Inputs**: Time horizon \( M \), restart period \( W \);
2: **for** \( m = 1, \ldots, M \) **do**
3:   **Set the initial state** \( x_1 = \alpha \)
4:   **if** \( m = e^m \) **then**
5:     \( Q_h^m(s,a), V_h^m(s) \leftarrow H - h + 1 \) **if** \( \beta > 0 \),
6:     \( Q_h^m(s,a), V_h^m(s) \leftarrow 0 \) **if** \( \beta < 0 \),
7:     \( N_h^m(s,a) \leftarrow 0 \) **for all** \((s,a,s') \in \mathcal{S} \times \mathcal{A} \times \mathcal{S} \); \( H \)
8:   **end if**
9: **for** \((s,a) \in \mathcal{S} \times \mathcal{A} \) **do**
10:   \( w_h^m(s,a) = \sum_{s'} \bar{P}_h^m(s'|s,a) [e^{\beta \bar{r}_h^m(s,a) + v_{\pi^m}(s')} \] \( = \) \( \min \{ e^{\beta(H-h+1)}, w_h^m(s,a) + \Gamma_h^m(s,a) \} \), \( \beta > 0; \)
11:   \( \max \{ e^{\beta(H-h+1)}, w_h^m(s,a) - \Gamma_h^m(s,a) \} \), \( \beta < 0; \)
12:   **end for**
13: **end for**
14: **for** \( h = 1, \ldots, H \) **do**
15:   **Take an action** \( a_h^m \leftarrow \arg \max_{a \in \mathcal{A}} \frac{1}{\beta} \log \{ G_h^m(s_h^m(a_h^m)) \}, \text{and observe} \]
16:   \( r_h^m(s_h^m, a_h^m) \) \( N_h^m(s_h^m, a_h^m) \leftarrow N_h^m(s_h^m, a_h^m, s_{h+1}^m) \) \( + \) \( 1; \)
17: **end for**
18: **end for**

for some constant \( C_1 > 1 \). Bonus terms of the form (6) are called “doubly decaying bonus” since they shrink deterministically and exponentially across the horizon steps due to the term \( e^{\beta(H-h+1)} \alpha \), apart from decreasing in the visit count. We refer the reader to (Fei, Yang, and Wang 2021) for more discussion.

#### 3.2 Periodically Restarted Risk-Sensitive Q-Learning

Next, we introduce Periodically Restarted Risk-sensitive Q-learning (Restart-RSQ) in Algorithm 2, which is model-free and inspired by RSQ2 in (Fei et al. 2021). Similar to Algorithm 1, we use the optimistic value evaluation to handle the exploration-exploitation trade-off and apply the restart strategy to adapt to the unknown non-stationarity. In particular, we re-initialize the value functions \( Q_h^m(s,a), V_h^m(s) \) and reset the visitation counter \( N_h^m(s,a) \) to zero every \( W \) episodes (line 5). The algorithm then updates the exponential Q values using the Q-learning style update (line 11-12) for the state action pair that just visited (line 8). The learning rate \( \alpha_t \) is defined as \( \frac{H+1}{H+1} \), which is motivated by (Jin et al. 2018)

7408
Algorithm 2: Periodically Restarted Risk-sensitive Q-learning (Restart-RSQ)

1: \textbf{Inputs}: Time horizon $M$, restart period $W$;
2: for $m = 1, \ldots, M$ do
3: \quad Set the initial state $x_1^m = x_1$ and $e^m = \left\lfloor \frac{m}{W} \right\rfloor - 1 \cdot W + 1$;
4: \quad if $m = e^m$ then
5: \quad \quad \quad $Q_h(s, a, V_m(s)) \leftarrow H - h + 1$ if $\beta > 0$,
6: \quad \quad \quad $Q_h(s, a, V_m(s)) \leftarrow 0$ if $\beta < 0$, $N_h^m(s, a) \leftarrow 0$ for all $(s, a, h) \in S \times A \times \{H\}$;
7: \quad end if
8: for $h = 1, \ldots, H$ do
9: \quad \quad Take an action $a^m_h \leftarrow \arg\max_{a' \in A} \frac{1}{\beta} \log \{G_h(s^m_h, a')\}$, and observe $r^m_h(s^m_h, a^m_h)$ and $s^m_{h+1}$;
10: \quad \quad $N_h(s_h^m, a_h^m) \leftarrow N_h(s_h^m, a_h^m) + 1$;
11: \quad \quad $t \leftarrow N_h(s_h^m, a_h^m)$;
12: \quad \quad $G_h(s^m_h, a^m_h) \leftarrow \min \left\{ e^{\beta(H-h+1)}, e^{\beta(H-h+1)} \left( 1 - \alpha_t \right) \cdot G_h(s^m_h, a^m_h) + \alpha_t \cdot \left[ e^{\beta(H-h+1)} \cdot \frac{1}{2} \log \{s^m_h, a^m_h\} + u_h(s^m_h, a^m_h) \right] \right\}$;
13: \quad \quad $V_h(s^m_h) \leftarrow \max_{a' \in A} \frac{1}{\beta} \log \{G_h(s^m_h, a')\}$;
14: end for
15: end for

and ensures that only the last $O\left( \frac{1}{\beta} \right)$ fraction of samples in each epoch is given non-negligible weights when used to estimate the optimistic Q-values under the non-stationarity. Algorithm 2 also applies the UCB by incorporating a "doubly decaying bonus" term that takes the form

$$
\Gamma_h^m(s^m_h, a^m_h) = C_2 \left( e^{\beta(H-h+1)} \right) - 1 \sqrt{h \log(MH)|S|A|A|\delta} \tag{7}
$$

for some constant $C_2 > 1$.

3.3 Theoretical Results and Discussions

We now present our main theoretical results for Algorithms 1 and 2.

Theorem 3.1 For every $\delta \in (0, 1)$, with probability at least $1 - \delta$ there exists a universal constant $c_1 > 0$ (used in Algorithm 1) such that the dynamic regret of Algorithm 1 with $W = M^{\frac{3}{2}} B^{-\frac{3}{2}} |S| |A|^{\frac{1}{2}}$ is bounded by

$$
\text{D-Regret}(M) \leq \tilde{O} \left( e^{\beta |H| |S| |A|^{\frac{1}{2}} H^2 M^{\frac{3}{2}} B^{\frac{1}{2}}} \right)
$$

Theorem 3.2 For every $\delta \in (0, 1)$, with probability at least $1 - \delta$ there exists a universal constant $c_2 > 0$ (used in Algorithm 2) such that the dynamic regret of Algorithm 2 with
Note that the dynamic regret can be bounded and decomposed as follows:

\[
D\text{-Regret}(M) \\
\leq \frac{1}{\beta} \sum_{m=1}^{M} (e^{\beta V_{1}^{*m}} - e^{\beta V_{1}^{m}}) + \frac{1}{\beta} \sum_{m=1}^{M} (e^{\beta V_{m}} - e^{\beta V_{1}^{m}}) \tag{8}
\]

where \(V_{1}^{m}\) is an UCB-based optimistic estimator of the value function as constructed in Algorithms 1 and 2. In a stationary environment with \(\beta > 0\), the base algorithms, such as Algorithms 1 and 2 without the restart mechanism (that is, \(W = M\)), ensure that \(R_{1}\) is simply non-positive and \(R_{2}\) is bounded by \(O(M^{\frac{3}{4}})\). However, in a non-stationary environment, both terms can be substantially larger. Thus, if we can detect the event that either of the two terms is abnormally larger than the promised bound for a stationary environment, we learn that the environment has changed substantially and should restart the base algorithm. This detection can be easily performed for \(R_{2}\) since both \(e^{\beta V_{1}^{m}}\) and \(e^{\beta V_{1}^{*m}}\) are observable \(^1\), but not for \(R_{1}\) since \(V_{1}^{*m}\) is unknown. To address this issue, we fully utilize the fact that \(e^{\beta V_{1}^{m}}\) is a UCB-based optimistic estimator to facilitate non-stationary detection.

We illustrate the idea of non-stationary detection for risk-sensitive RL in Figure 1. Here, the value of \(V_{1}^{*m}\) drastically increases which results to an increase in \(e^{\beta V_{1}^{*m}}\) for \(\beta > 0\) and an decrease in \(e^{\beta V_{1}^{*m}}\) for \(\beta < 0\). If we start running another instance of base algorithm after this environment change, then its performance will gradually approach due to its regret guarantee in a stationary environment. Since the optimistic estimators should always be an upper bound of the learner’s average performance in a stationary environment for \(\beta > 0\) or a lower bound of the learner’s average performance in a stationary environment for \(\beta < 0\), if, at some point, we find that the new instance of the base algorithm significantly outperforms/underperforms (depending on the value of \(\beta\)) this quantity, we can infer that the environment has changed.

\[\text{Figure 1: An illustration of the risk-sensitive non-stationarity detection. The green curves represent the learner’s average performance in new ALG. Since both } U_{m} \text{ and learner’s average performance depend on the risk-sensitive parameter } \beta \text{ in a non-linear way. The non-stationarity detection relies on the choice of } \beta \text{ and thus the risk control and the handling of the non-stationarity can not be separately designed.}\]

\[\text{MALG partitions the block equally into } 2^{n-k} \text{ sub-intervals of length } 2^{k} \text{ for } k = 0, 1, \ldots, n, \text{ and an instance of based algorithm (denoted by ALG) is scheduled for each of these sub-intervals with probability } \rho(2^{n-k}) \text{ where } \rho \text{ is a non-increasing function associated with the bound on } R_{2} \text{ for ALG in a stationary environment (see Appendix). We refer to these instances of length } 2^{k} \text{ as order-}k \text{ instances.}\]

**4.2 Multi-Scale ALG (MALG) and Non-Stationarity Tests**

To detect the non-stationarity at different scales, we schedule and run instances of the base algorithm ALG in a randomized and multi-scale manner. In particular, Adaptive-ALG runs MALG in a sequence of blocks with doubling lengths. Within each block, Adaptive-ALG first initializes a MALG schedule (see Appendix), and then interacts with the unique active instance at each episode with the environment (lines 5-7 in Algorithm 3). At the end of each episode, Adaptive-ALG performs two non-stationarity tests (line 10 in Algorithm 3), and if either of them returns fail, the restart is triggered. We now describe these three parts in detail below.

**MALG-initialization.** MALG is run for an interval of length \(2^{\tau}\) (unless it is terminated by the non-stationarity detection), which is called a **block**. During the initialization,

\[^{1}\text{More precisely, } \sum_{m=1}^{M} e^{\beta V_{1}^{*}} \text{ can be estimated from } \sum_{m=1}^{M} e^{\beta \sum_{i=1}^{t} \tau_{r}} \text{ using the Azuma’s inequality.}\]

\[^{1}\text{More precisely, } \sum_{m=1}^{M} e^{\beta V_{1}^{*}} \text{ can be estimated from } \sum_{m=1}^{M} e^{\beta \sum_{i=1}^{t} \tau_{r}} \text{ using the Azuma’s inequality.}\]
a certain amount. On the other hand, Test2 prevents R2 from growing too large by directly testing if its average is large than the promised regret bound. The two non-stationarity tests for β < 0 are similar but with \( \frac{1}{2^g} \sum_{r=alg.s} R_r \) and \( U_m \) exchanged in TEST1, as well as with \( g_r \) and \( R_r \) exchanged in TEST2.

### 4.3 Theoretical Results and Discussions

For simplicity, we denote the revised Algorithms 1 and 2 without the restart mechanism (that is, \( W = M \)) as RSMB and RSQ, respectively. We now present our main theoretical result for Algorithm 3 when the base algorithms are RSMB and RSQ, respectively.

**Theorem 4.1** For every \( \delta \in (0, 1] \), with probability at least
\[
1 - \delta \text{\ it holds for Algorithm 3 that }
\]
\[
\begin{align*}
\text{D-Regret}(M) & \leq \begin{cases} 
\tilde{O} \left( e^{\|H\| |S|^{\frac{1}{2}} |A|^{\frac{1}{2}} H^2 M^{\frac{1}{2}} B^{\frac{1}{2}}} \right), & \text{if ALG is RSMB,} \\
\tilde{O} \left( e^{\|H\| |S|^{\frac{1}{2}} |A|^{\frac{1}{2}} H^2 M^{\frac{1}{2}} B^{\frac{1}{2}}} \right), & \text{if ALG is RSQ.}
\end{cases}
\end{align*}
\]

The above results show that the dynamic regret bound of the adaptive Algorithm 3 (almost) matches that of the restart Algorithms 1-2 that require the knowledge of the variation budget. The proof of Theorem 4.1 relies on the results in Theorems 3.1-2 and is provided in Appendix.

### 5 Lower Bound

We now present a lower bound on the dynamic regret which complements the upper bounds in Theorems 3.1, 3.2 and 4.1.

**Theorem 5.1** For sufficiently large \( M \), there exists an instance of non-stationary MDP with \( H \) horizons, state space \( S \), action space \( A \) and variation budget \( B \) such that
\[
\text{D-Regret}(M) \geq \Omega \left( \frac{e^{\|H\| |S|^{\frac{1}{2}} |A|^{\frac{1}{2}} M^{\frac{1}{2}} B^{\frac{1}{2}}}}{\|H\| |S|^{\frac{1}{2}} |A|^{\frac{1}{2}} \} \right).
\]

Theorem 5.1 shows that the exponential dependence on \( |\beta| \) and \( H \) in Theorems 3.1, 3.2 and 4.1 are essentially indispensable and that the results in Theorems 3.1, 3.2 and 4.1 are nearly optimal in their dependence on \( |A|, M \) and \( B \). When \( \beta \to 0 \), we recover the existing lower bound for the non-stationary risk-neutral episodic MDP problems (Mao et al. 2020).

The proof is given in Appendix. In the proof, the hard instance we construct is a non-stationary MDP with piecewise constant dynamics on each segment of the horizon, and its dynamics experience an abrupt change at the beginning of each new segment. In each segment, we construct a \(|S||A|\)-arm bandit model with Bernoulli reward for each arm. This bandit model can be seen as a special case of our episodic MDP problem, and then we show the expected regret, in terms of the logarithmic-exponential objective, that any bandit algorithm has to incur.

### 6 Risk Control Under the Non-stationarity

Risk control in non-stationary RL is more challenging since the rewards and dynamics are time-varying and unknown. In this section, we discuss some key ideas behind our methods and proofs.

- **Normalized dynamics estimation in model-based algorithm.** In model-based algorithms for non-stationary risk-neutral RL, the un-normalized dynamics estimation (Domíngues et al. 2021; Ding and Lavaei 2022) is sufficient for achieving a near-optimal regret because the effect of the model estimation error due to the “unnormalization” on the dynamic regret is little. However, it is critical to use the normalized dynamics estimation (5a) in Algorithm 1. This is because that a small model estimation error due to the “unnormalization” may be amplified when \( \beta \to 0 \). We note that the stationary version of our Algorithm 1 is also the first model-based algorithm with a theoretical guarantee for stationary risk-sensitive RL problems in the literature.

- **Multiplicative feature of the exponential Bellman equation.** The multiplicative feature of the exponential Bellman equation will involve the policy evaluation error as multiplicative terms. These terms are easy to bound in a stationary environment in light of the optimistic estimator of the exponential value function. However, due to the non-stationary drifting of the environment, the estimator \( V^\text{em} \) may no longer be an optimistic estimator and the errors of the optimistic estimator are all in the form of a multiplicative way due to the nature of the exponential Bellman equation. We need to introduce additional terms to guarantee each multiplicative terms are non-negative as in the proof of Theorem 3.2.

- **Non-stationarity detection on the exponential value functions.** Different from non-stationarity detection for risk-neutral RL (Wei and Luo 2021), we design non-stationarity detection mechanism for the exponential value functions (3) instead of the value functions (1) in Algorithm 3. This is because the non-linearity of the risk-sensitive value function makes it difficult to obtain its unbiased estimation, which is needed in the design of non-stationary detection mechanism.

### Separation design of the risk-control and the non-stationarity.

When the variation budget is known, the risk-control and the handling of the non-stationarity can be separately designed in the algorithm, that is, the restart frequency in Algorithms 1 and 2 does not depend on the risk parameter \( \beta \) and only depends on the non-stationarity of the environment \( B \). If we know the environment’s variation budget in advance, then we can schedule the non-stationarity risk-consciousness in advance. When \( \beta \to 0 \), we recover the existing lower bound for the non-stationary risk-neutral episodic MDP problems (Mao et al. 2020).

The proof is given in Appendix. In the proof, the hard instance we construct is a non-stationary MDP with piecewise constant dynamics on each segment of the horizon, and its dynamics experience an abrupt change at the beginning of each new segment. In each segment, we construct a \(|S||A|\)-arm bandit model with Bernoulli reward for each arm. This bandit model can be seen as a special case of our episodic MDP problem, and then we show the expected regret, in terms of the logarithmic-exponential objective, that any bandit algorithm has to incur.
