Abstract

The matrix-based Rényi’s entropy allows us to directly quantify information measures from given data, without explicit estimation of the underlying probability distribution. This intriguing property makes it widely applied in statistical inference and machine learning tasks. However, this information theoretical quantity is not robust against noise in the data, and is computationally prohibitive in large-scale applications. To address these issues, we propose a novel measure of information, termed low-rank matrix-based Rényi’s entropy, based on low-rank representations of infinitely divisible kernel matrices. The proposed entropy functional inherits the speciality of the original definition to directly quantify information from data, but enjoys additional advantages including robustness and effective calculation. Specifically, our low-rank variant is more sensitive to informative perturbations induced by changes in underlying distributions, while being insensitive to uninformative ones caused by noises. Moreover, low-rank Rényi’s entropy can be efficiently approximated by random projection and Lanczos iteration techniques, reducing the overall complexity from \( O(n^3) \) to \( O(n^2s) \) or even \( O(ns^2) \), where \( n \) is the number of data samples and \( s \ll n \). We conduct large-scale experiments to evaluate the effectiveness of this new information measure, demonstrating superior results compared to matrix-based Rényi’s entropy in terms of both performance and computational efficiency.

Introduction

The practical applications of traditional entropy measures, e.g. Shannon’s entropy (Shannon 1948) and Rényi’s entropy (Rényi 1961) have long been hindered by their heavy reliance on the underlying data distributions, which are extremely hard to estimate or even intractable in high-dimensional spaces (Fan and Li 2006). Alternatively, the matrix-based Rényi’s entropy proposed by (Sanchez Giraldo, Rao, and Principe 2014) treats the entire eigenspectrum of a normalized kernel matrix as a probability distribution, thus allows direct quantification from given data samples by projecting them in reproducing kernel Hilbert spaces (RKHS) without the exhausting density estimation. This intriguing property makes matrix-based Rényi’s entropy and its multivariate extensions (Yu et al. 2019) successfully applied in various data science applications, ranging from classical dimensionality reduction and feature selection (Brockmeier et al. 2017; Álvarez-Meza et al. 2017) problems to advanced deep learning problems such as network pruning (Sarvani et al. 2021) and knowledge distillation (Miles, Rodríguez, and Mikolajczyk 2021).

Despite the empirical success of matrix-based Rényi’s entropy, it has been shown to be not robust against noises in the data (Yu et al. 2019), because it cannot distinguish them from linear combinations of informative features in high-dimensional scenarios. Moreover, the exact calculation requires \( O(n^3) \) time complexity with traditional eigenvalue decomposition techniques e.g. CUR decomposition and QR factorization (Mahoney and Drineas 2009; Watkins 2008), greatly hampering its application in large scale tasks due to the unacceptable computational cost.

Inspired by the success of min-entropy which uses the largest outcome solely as a measure of information (Wan et al. 2018; Konig, Renner, and Schaffner 2009), we seek for a robust information quantity by utilizing low-rank representations of kernel matrices. Our new definition, termed low-rank matrix-based Rényi’s entropy (abbreviated as low-rank Rényi’s entropy), fulfills the entire set of axioms provided by Rényi (Rényi 1961) that a function must satisfy to be considered a measure of information. Compared to the original matrix-based Rényi’s entropy, our low-rank variant is more sensitive to informative perturbations caused by variation of the underlying probability distribution, while being more robust to uninformative ones caused by noises in the data samples. Moreover, our low-rank Rényi’s entropy can be efficiently approximated by random projection and Lanczos iteration techniques, achieving substantially lower time complexity than the trivial eigenvalue decomposition approach. We theoretically analyze the quality of approximation results, and conduct large-scale experiments to evaluate the effectiveness of low-rank Rényi’s entropy as well as the approximation algorithms. The main contributions of this work are summarized as follows:

- We extend Giraldo et al.’s definition and show that a measure of entropy can be built upon the low-rank representation of the kernel matrix. Our low-rank definition can be naturally extended to measure the interactions between multiple random variables, including joint entropy,
conditional entropy, and mutual information.

- Theoretically, we show that low-rank Rényi’s entropy is more insensitive to random perturbations of the data samples under mild assumptions. We also give empirical examples of low-rank Rényi’s entropy achieving higher discriminability for different eigenspectrum distributions through a proper choice of the hyper-parameter $k$.

- We develop efficient algorithms to approximate low-rank Rényi’s entropy through random projection and Lanczos iteration techniques, enabling fast and accurate estimations respectively. The overall complexity is reduced from $O(n^3)$ to $O(n^2s)$ or even $O(ns^2)$ for some $s < n$, leading to a significant speedup compared to the original matrix-based Rényi’s entropy.

- We evaluate the effectiveness of low-rank Rényi’s entropy on large-scale synthetic and real-world datasets, demonstrating superior performance compared to the original matrix-based Rényi’s entropy while bringing tremendous improvements in computational efficiency.

### Related Work

#### Matrix-based Rényi’s Entropy

Given random variable $X$ with probability density function (PDF) $p(x)$ defined in a finite set $X$, the $\alpha$-order Rényi’s entropy ($\alpha > 0, \alpha \neq 1$) $H_\alpha(X)$ is defined as

$$H_\alpha(X) = \frac{1}{1-\alpha} \log_2 \int_X p^\alpha(x) \, dx,$$

where the limit case $\alpha \to 1$ yields the well-known Shannon’s entropy. It is easy to see that Rényi’s entropy relies heavily on the distribution of the underlying variable $X$, preventing its further adoption in data-driven science, especially for high-dimensional scenarios. To alleviate this issue, an alternative measure namely matrix-based Rényi’s entropy was proposed (Sanchez Giraldo, Rao, and Principe 2014):

**Definition 1.** Let $\kappa : X \times X \mapsto \mathbb{R}$ be an infinitely divisible positive kernel (Bhatia 2006). Given $\{x_i\}_{i=1}^n \subset X$, each $x_i$ being a real-valued scalar or vector, and the Gram matrix $K$ obtained from $K_{ij} = \kappa(x_i, x_j)$, a matrix-based analogue of Rényi’s $\alpha$-entropy can be defined as:

$$S_\alpha(A) = \frac{1}{1-\alpha} \log_2 \left( \sum_{i=1}^n \lambda_i^\alpha(A) \right),$$

where $A_{ij} = \frac{1}{n} K_{ij}$ is a normalized kernel matrix and $\lambda_i(A)$ is the $i$-th largest eigenvalue of $A$.

The kernel matrix $A$ is positive semi-definite (PSD) and satisfies $\text{tr}(A) = 1$, therefore $\lambda_i \in [0, 1]$ for all $i \in [1, n]$. With this setting, one can similarly define matrix notion of Rényi’s conditional entropy $S_\alpha(A|B)$, mutual information $I_\alpha(A; B)$, and their multivariate extensions (Yu et al. 2019).

#### Approximating Matrix-based Rényi’s Entropy

Exactly calculating $S_\alpha(A)$ requires $O(n^3)$ time complexity in general with traditional eigenvalue decomposition techniques. Recently, several attempts have been made towards accelerating the computation of $S_\alpha(A)$ from the perspective of randomized numerical linear algebra (Gong et al. 2021; Dong et al. 2022). Although we also develop fast approximations, the motivation and technical solutions are totally different: we aim to propose a new measure of information that is robust to noise in data and also enjoys fast computation, whereas Gong and Dong et al. only accelerate the original matrix-based Rényi’s entropy. Moreover, in terms of adopted mathematical tools, we mainly focus on random projection and Lanczos iteration algorithms, rather than stochastic trace estimation and polynomial approximation techniques used in their works. As a result, the corresponding theoretical error bounds are also different.

#### A Low-rank Definition of Rényi’s Entropy

Our motivations root in two observations. Recall that the min-entropy (Konig, Renner, and Schaffner 2009), defined by $H_{\text{min}}(X) = -\log_2 \max_{x \in X} p(x)$, measures the amount of information using solely the largest probability outcome. In terms of quantum statistical mechanics, it is the largest eigenvalue of the quantum state $\rho$ which is PSD and has unit trace (Ohya and Petz 2004). On the other hand, the eigenvalues with the maximum magnitude characterize the main properties of a PSD matrix. Inspired by these observations, we develop a robust information theoretical quantity by exploiting the low-rank representation:

**Definition 2.** Let $\kappa : X \times X \mapsto \mathbb{R}$ be an infinitely divisible positive kernel. Given $\{x_i\}_{i=1}^n \subset X$ and integer $k \in [1, n-1]$, the low-rank Rényi’s $\alpha$-order entropy is defined as:

$$S^k_\alpha(A) = \frac{1}{1-\alpha} \log_2 \left( \sum_{i=1}^k \lambda_i^\alpha(A) + (n-k)\lambda_k^\alpha(A) \right),$$

where $A$ is the normalized kernel matrix constructed from $\{x_i\}_{i=1}^n$ and $\lambda_i(A)$ is the $i$-th largest eigenvalue of $A$ and $\lambda_k(A) = \frac{1}{n-k} (1 - \sum_{i=1}^k \lambda_i(A))$.

Let $L_k(A)$ be the best rank-$k$ approximation of $A$ and $L_k(A)$ be the matrix constructed by replacing the smallest $n-k$ eigenvalues in $A$ to $\lambda_k(A)$. It is easy to verify that $S^k_\alpha(A) = S^k_\alpha(A_k) = S^k_\alpha(L_k(A)) = S^k_\alpha(L_k(A))$. Definition 2 complements the smaller eigenvalues through a uniform distribution, which is the unique method that fulfills all axioms below (the uniqueness is discussed in the appendix\(^1\)).

**Proposition 1.** Let $A, B \in \mathbb{R}^{n \times n}$ be arbitrary normalized kernel matrices, then

\begin{itemize}
  \item[(a)] $S^k_\alpha(PAP^T) = S^k_\alpha(A)$ for any orthogonal matrix $P$.
  \item[(b)] $S^k_\alpha(pA)$ is a continuous function for $0 < p \leq 1$.
  \item[(c)] $0 \leq S^k_\alpha(A) \leq S^k_\alpha(D)$.
  \item[(d)] $S^{2nk-k^2}_\alpha(L_k(A) \otimes L_k(B)) = S^k_\alpha(A) + S^k_\alpha(B)$.
  \item[(e)] If $AB = BA = 0$ and $\text{tr}(A_k) = \text{tr}(B_k) = 1$, then for $g(x) = 2^{(1-\alpha)x}$ and $t \in [0, 1]$, we have $S^{t\alpha}_\alpha(tA + (1-t)B) = g^{-1}(tg(S^{t\alpha}_\alpha(A)) + (1-t)g(S^{t\alpha}_\alpha(B)))$.
  \item[(f)] $S^k_\alpha\left(\frac{A-B}{\text{tr}(A+B)}\right) \geq \max\{S^k_\alpha(A), S^k_\alpha(B)\}$.
  \item[(g)] $S^k_\alpha\left(\frac{A-B}{\text{tr}(A+B)}\right) \leq S^k_\alpha(A) + S^k_\alpha(B)$.
\end{itemize}

\(^{1}\)https://github.com/Gameiapymno/RLMI
Remark 1. Proposition 1 characterizes the basic properties of low-rank Rényi’s entropy, in which (a)-(e) are the set of axioms provided by Rényi (Rényi 1961) that a function must satisfy to be a measure of information. Additionally, (f) and (g) together imply a definition of joint entropy which is also compatible with the individual entropy measures:

\[ S_{\alpha}^{k}(A, B) = S_{\alpha}^{k}\left(\frac{A \circ B}{\text{tr}(A \circ B)}\right). \]

This further allows us to define the low-rank conditional entropy \( S_{\alpha}^{k}(A|B) \) and mutual information \( I_{\alpha}^{k}(A; B) \), whose positiveness is guaranteed by (f) and (g) respectively:

\[ S_{\alpha}^{k}(A|B) = S_{\alpha}^{k}(A) - S_{\alpha}^{k}(A, B), \]
\[ I_{\alpha}^{k}(A; B) = S_{\alpha}^{k}(A) + S_{\alpha}^{k}(B) - S_{\alpha}^{k}(A, B). \]

An intuitive overview of the comparative behavior between \( S_{\alpha}(A) \) and \( S_{\alpha}^{k}(A) \) for \( n = 1000 \) is reported in Figure 1 and 2, where we evaluate the impact of \( k, \alpha \) and eigenspectrum decay rate (EDR) \( r \) respectively. The eigenvalues are initialized by \( \lambda_i = \varepsilon^{-r_i/n} \) and then normalized. It can be observed from Figure 1 that \( S_{\alpha}^{k}(A) \) is always larger than \( S_{\alpha}(A) \) since the uncertainty of the latter \( n - k \) outcomes are maximized. Moreover, \( S_{\alpha}^{k}(A) \) quickly converges to \( S_{\alpha}(A) \) with the increase of \( k \), especially in extreme cases when the eigenspectrum of \( A \) is flat or steep. From Figure 2, we can see that for small \( k \), \( S_{\alpha}^{k}(A) \) decreases slow with the increase of \( \alpha \) when \( \alpha < 1 \) and fast otherwise. This behavior is the opposite when \( k \) becomes large. Furthermore, we can see that EDR directly influences the value of entropy, as a flat eigenspectrum indicates higher uncertainty and steep the opposite. As can be seen, \( S_{\alpha}^{k}(A) \) monotonically decreases with the increase of \( r \), and decreases faster than \( S_{\alpha}(A) \) in a certain range which varies according to the choice of \( k \), indicating higher sensitivity to informative distribution changes when the hyper-parameter \( k \) is selected properly.

Moreover, consider the case that the data samples \( \{x_i\}_{i=1}^{n} \) are randomly perturbed, i.e. \( y_i = x_i + \varepsilon p_i \), where \( p_i \) are random vectors comprised of i.i.d. entries with zero expectation and unit variance. Let \( A \) and \( B \) be kernel matrices constructed from \( \{x_i\}_{i=1}^{n} \) and \( \{y_i\}_{i=1}^{n} \) respectively, and let \( \{\lambda_i\}_{i=1}^{n}, \{\mu_i\}_{i=1}^{n} \) be their eigenvalues. Then it satisfies that \( \mu_i \approx \lambda_i + u_i (B - A) u_i \) (Ngo 2005), where \( u_i \) is the corresponding eigenvector of \( \lambda_i \). When \( \varepsilon \) is small, the entries as well as the eigenvalues of \( A \) are nearly independently perturbed. The following theorem shows that \( S_{\alpha}^{k}(A) \) is more robust against small noises in data compared to \( S_{\alpha}(A) \):

Theorem 1. Let \( \{\nu_i\}_{i=1}^{n} \) be independent random variables with zero mean and variance \( \{\sigma^2_i\}_{i=1}^{n} \). Let \( A \) and \( B \) be PSD matrices with eigenvalues \( \lambda_i \) and \( \mu_i \) respectively. If \( \sum_{i=1}^{n} \sigma^2_i \leq \sum_{i=k+1}^{n} \sigma^2_i \) or \( \alpha > 1 \), there exists \( \varepsilon > 0 \) such that when all \( |\nu_i| \leq \varepsilon \), we have \( \text{Var}[I_{\alpha}^{k}(B)] \leq \text{Var}[I_{\alpha}(B)] \), where \( I_{\alpha} \) is the information potential (Gokcay and Principe 2000) defined as \( I_{\alpha}(B) = 2(1-\alpha)S_{\alpha}(B) \) and \( I_{\alpha}^{k}(B) = 2(1-\alpha)S_{\alpha}^{k}(B) \).

Remark 2. Theorem 1 indicates that \( I_{\alpha}^{k}(B) \) enables lower variance than \( I_{\alpha}(B) \) against random perturbation of the eigenvalues under mild conditions, which is easy to be satisfied since in most cases we have \( k \ll n \). Combining with our discussion above, the low-rank Rényi’s entropy is more sensitive to informative variations in probability distributions which will surely induce an increase or decrease in entropy, while being insensitive to uninformative perturbations caused by noises in the data samples.

Extending to Multivariate Scenarios

Following Definition 2 and Proposition 1, the low-rank variant of multivariate Rényi’s joint entropy, in virtue of the Venn diagram relation for Shannon’s entropy (Yeung 1991), could be naturally derived:

Definition 3. Let \( \{\kappa_i\}_{i=1}^{L} : \mathcal{X}^i \times \mathcal{X}^i \rightarrow \mathbb{R} \) be positive infinitely divisible kernels and \( \{x_i^1, \cdots, x_i^L\}_{i=1}^{n} \subset \mathcal{X}^1 \times \cdots \times \mathcal{X}^L \), the low-rank Rényi’s joint entropy is defined as:

\[ S_{\alpha}^{k}(A_1, \cdots, A_L) = S_{\alpha}^{k}\left(\frac{A_1 \circ \cdots \circ A_L}{\text{tr}(A_1 \circ \cdots \circ A_L)}\right), \]

where \( A_1, \cdots, A_L \) are normalized kernel matrices constructed from \( \{x_i^1\}_{i=1}^{n}, \cdots, \{x_i^L\}_{i=1}^{n} \) respectively and \( \circ \) denotes the Hadamard product.

This joint entropy definition enables further extension to multivariate conditional entropy and mutual information:

\[ S_{\alpha}^{k}(A_1, \cdots, A_k; B) = S_{\alpha}^{k}(A_1, \cdots, A_k, B) - S_{\alpha}^{k}(B), \]
\[ I_{\alpha}^{k}(A_1, \cdots, A_k; B) = S_{\alpha}^{k}(A_1, \cdots, A_k) + S_{\alpha}^{k}(B) - S_{\alpha}^{k}(A_1, \cdots, A_k, B), \]
Algorithm 1: Approximation via Random Projection

1: Input: Integers \( n, k \in [1, n/2] \), \( s \geq k \), kernel matrix \( A \in \mathbb{R}^{n \times n} \), order \( \alpha > 0 \).
2: Output: Approximation to \( S_k^\alpha(A) \).
3: Construct a random projection matrix \( P \in \mathbb{R}^{n \times s} \).
4: Calculate \( \hat{A} = AP \in \mathbb{R}^{n \times s} \).
5: Calculate the largest \( k \) singular values \( \hat{\lambda}_i \), \( i \in [1, k] \) of \( \hat{A} \) through singular value decomposition.
6: Calculate \( \hat{\lambda}_r = \frac{1}{n/k} \left( 1 - \sum_{i=1}^{k} \hat{\lambda}_i \right) \).
7: Return: \( S_k^\alpha(A) = \frac{1}{1-\alpha} \log_2 \left( \sum_{i=1}^{k} \frac{1}{\alpha} \hat{\lambda}_i^\alpha + (n-k)\hat{\lambda}_r^\alpha \right) \).

where \( A_1, \ldots, A_L \) and \( B \) are normalized kernel matrices constructed from the variables \{\( x_i^1 \}_{i=1}^n, \ldots, \{x_i^L \}_{i=1}^n \) and the target label \{\( y_i \)\}_{i=1}^n respectively. Their positiveness can be guaranteed through a reduction to axiom (f) and (g). These multivariate information quantities enable much more widespread applications e.g. feature selection, dimension reduction and information-based clustering.

Approximating Low-rank Rényi’s Entropy

Although only the largest eigenvalues are accessed by our entropy definition, one still needs to calculate the full eigen-spectrum of the PSD matrix \( A \) through eigenvalue decomposition algorithms, resulting in \( O(n^3) \) overall time cost. To alleviate the computational burden, we design fast approximations by leveraging random projection and Lanczos iteration techniques for low-rank Rényi’s entropy.

Random Projection Approach

Random projection offers a natural way to approximate the low-rank representation of kernel matrices. The core idea is to project the \( n \times n \) PSD matrix \( A \) into a \( n \times s \) subspace, and then use the largest \( k \) singular value of the projected matrix as approximations of the largest \( k \) eigenvalues, as summarized in Algorithm 1. In this way, the main computation cost is reduced to \( O(ns^2) \) or even \( O(ns^2) \), \( s \ll n \), substantially lower than the original \( O(n^3) \) approach. Based on this fact, we develop efficient approximation algorithms by exploring different random projection techniques, in which the construction of \( P \) varies depending on the practical applications, ranging from simple but effective Gaussian distributions to advanced random orthogonal projections.

Gaussian Random Projection

As one of the most widely used random projection techniques, Gaussian random projection (GRP) admits a simple but elegant solution for eigenvalue approximation:

\[
P = \sqrt{n/s} \cdot G,
\]

where the columns of \( G \in \mathbb{R}^{n \times s} \) are initialized by i.i.d random standard Gaussian variables and then orthogonalized. The time complexity of GRP is \( O(ns^2) \).

Subsampled Randomized Hadamard Transform

SRHT (Lu et al. 2012; Tropp 2011) is a simplification of the fast Johnson-Lindenstrauss transform (Ailon and Chazelle 2009) which preserves the geometry of an entire subspace of vectors compared to GRP. In our settings, the \( n \times s \) SRHT matrix is constructed by

\[
P = \sqrt{1/s} \cdot \text{DHS},
\]

where \( D \in \mathbb{R}^{n \times n} \) is a diagonal matrix with random \{\( \pm 1 \)\} entries, \( H \in \mathbb{R}^{n \times n} \) is a Walsh-Hadamard matrix, \( S \in \mathbb{R}^{n \times s} \) is a subsampling matrix whose columns are a uniformly chosen subset of the standard basis of \( \mathbb{R}^n \).

Two key ingredients make SRHT an efficient approximation strategy: first, it takes only \( O(n^2 \min(\log(n), s)) \) time complexity to calculate the projected matrix \( \hat{A} \); second, the orthonormality between the columns of \( A \) can be preserved after projection, thus is more likely to achieve lower approximation error compared to GRP.

Input-Sparsity Transform

Similar to SRHT, input-sparsity transform (IST) (Mahoney 2011; Woodruff and Zandieh 2020) utilizes the fast John-Lindenstrauss transform to reduce time complexity for least-square regression and low-rank approximation:

\[
P = \sqrt{n/s} \cdot DS,
\]

where \( D \) and \( S \) are constructed in the same way as SRHT. The complexity of calculating \( A \) using IST is \( O(nz(A)) \), where \( nz \) denotes the number of non-zero entries, resulting in a total complexity of \( O(\min(nz(A), ns^2)) \).

Sparse Graph Sketching

The idea of using sparse graphs as sketching matrices is proposed in (Hu et al. 2021). It is shown that the generated bipartite graphs by uniformly adding edges enjoy elegant theoretics properties known as the Expander Graph or Magic Graph with high probability, and thus serve as an effective random projection strategy:

\[
P = \sqrt{1/p} \cdot G,
\]

where \( p \in \mathbb{N} \) is the hyper-parameter that controls the sparsity, and each column \( g \) of \( G \) is constructed independently by uniformly sampling \( c \in [n] \) with \( |c| = p \), and then setting \( g_i = \{\pm 1\} \) randomly for \( i \in c \) and \( g_i = 0 \) for \( i \notin c \). Similar to IST, sparse graph sketching (SGS) also utilizes the sparsity of input matrices and achieves \( O(nz(A)p) \) computational complexity to calculate the projected matrix.

Theoretical Results

Next, we provide the main theorem on characterizing the quality-of-approximation for low-rank Rényi’s entropy:

**Theorem 2.** Let \( A \) be positive definite and

\[
S = \begin{cases}
O((k + \log(1/\delta)/\epsilon_0^2)), & \text{for GRP} \\
O((k + \log n) \log k/\epsilon_0^2), & \text{for SRHT} \\
O(k^2/\epsilon_0^2), & \text{for IST} \\
O(k \log(k/\delta \epsilon_0)/\epsilon_0^2), & \text{for SGS} \\
O(\log(k/\delta \epsilon_0)/\epsilon_0), & \text{for SGS}
\end{cases}
\]

where \( \epsilon_0 = \epsilon \lambda_0 \lambda_r \), then for \( k \leq n/2 \), with confidence at least \( 1 - \delta \), the output of Algorithm 1 satisfies

\[
|\hat{\lambda}_i^2 - \lambda_i^2| \leq \epsilon
\]
Algorithm 2: Approximation via Lanczos Iteration

1: Input: Integers $n$, $k \in [1, n/2]$, $s \geq k$, kernel matrix $A \in \mathbb{R}^{n \times n}$, order $\alpha > 0$, initial vector $q$.
2: Output: Approximation to $S^k_n(G)$.
3: Set $q_0 = 0$, $\beta_0 = 0$, $q_1 = q/\|q\|$. 
4: for $j = 1, 2, \ldots, s$ do
5: $q_{j+1} = Aq_j - \beta_{j-1}q_{j-1}$, $\gamma_j = (q_{j+1}, q_j)$.
6: $\beta_j = \|q_{j+1}\|$, $q_{j+1} = q_{j+1}/\beta_j$.
7: end for
8: Calculate the largest $k$ eigenvalues $\hat{\lambda}_i$, $i \in [1, k]$ of

$$
T = \begin{bmatrix}
\gamma_1 & \beta_1 & 0 \\
\beta_1 & \gamma_2 & \beta_2 \\
o & \beta_{s-1} & \gamma_s \\
\end{bmatrix}.
$$

9: Calculate $\hat{\lambda}_i = \frac{1}{1-\alpha}(1 - \sum_{i=1}^{k} \hat{\lambda}_i^n + (n-k)\hat{\lambda}_i^n).

10: Return: $\tilde{S}^k_n(A) = \frac{1}{1-\alpha} \log_2 \left( \sum_{i=1}^{k} \hat{\lambda}_i^n + (n-k)\hat{\lambda}_i^n \right)$.

for all $i \in [1, k]$ eigenvalues of $A$ and

$$
|S^k_n(A) - \tilde{S}^k_n(A)| \leq |\frac{1}{1-\alpha} \log_2(1-\epsilon)|.
$$

**Remark 3.** Theorem 2 provides the accuracy guarantees for low-rank Rényi’s entropy approximation via random projections. It can be observed that the approximation error grows with the increase of $\alpha$ when $\alpha$ is small. Note that although the error bound is additive in nature, it can be further reduced to a relative error bound under mild condition $S^k_n(G) \geq \sqrt{c}$. In general, Theorem 2 requires $s = O(k + 1/\epsilon^2)$ to achieve $1 \pm \epsilon$ absolute accuracy, which is consistent with the complexity results of least squares and low rank approximations (Mahoney 2011).

**Lanczos Iteration Approach**

Besides random projection, the Lanczos algorithm is also widely adopted to find the $k$ extreme (largest or smallest in magnitude) eigenvalues and the corresponding eigenvectors of an $n \times n$ Hermitian matrix $A$. Given an initial vector $q$, the Lanczos algorithm utilizes the Krylov subspace spanned by $\{q, Aq, \ldots, A^s q\}$ to construct an tridiagonalization of $A$ whose eigenvalues converge to those of $A$ along with the increase of $s$, and are satisfactorily accurate even for $s \ll n$. As shown in Algorithm 2, the main computation cost is the $O(n^2s)$ matrix-vector multiplications in the Lanczos process, which could be further reduced to $O(nmu(A)s)$ when $A$ is sparse. The computational cost of reorthogonalization can be further alleviated by explicit or implicit restarting Lanczos methods. The following theorem establishes the accuracy guarantee of Algorithm 2:

**Theorem 3.** Let $A$ be positive definite, $q$ be the initial vector, $\{\phi_i\}_{i=1}^k$ be the corresponding eigenvectors and

$$
s = \left[k + \frac{1}{2\log R} \log \left( \frac{\alpha^2 k^2 \lambda_1}{\epsilon \lambda_r} \right) \right],
$$

where

$$
R = \gamma + \sqrt{\gamma^2 - 1}, \quad \gamma = 1 + 2 \min \{5, k\} \frac{\lambda_i - \lambda_{i+1}}{\lambda_{i+1} - \lambda_n},
$$

$$
\theta = \max_{i \in [1, k]} \tan(\phi_i, q), \quad K = \prod_{j=1}^{k-1} \frac{\lambda_j - \lambda_{j+1}}{\lambda_j - \lambda_k},
$$

then for $k \leq n/2$, the output of Algorithm 2 satisfies

$$
0 \leq \lambda_i - \hat{\lambda}_i \leq \epsilon \lambda_i
$$

for all $i \in [1, k]$ eigenvalues of $A$ and

$$
|S^k_n(A) - \tilde{S}^k_n(A)| \leq |\frac{\alpha}{1-\alpha} \log_2(1-\epsilon)|.
$$

**Experimental Results**

In this section, we evaluate the proposed low-rank Rényi’s entropy and the approximation algorithms under large-scale experiments. Our experiments are conducted on an Intel 17-10700 (2.90GHz) CPU and an RTX 2080Ti GPU with 64GB of RAM. The algorithms are implemented in C++ with the Eigen library and in Python with the Pytorch library.

**Simulation Studies**

We first test the robustness of $S^k_n(A)$ against noises in the data. As indicated by Theorem 1, low-rank Rényi’s entropy achieves lower variance under mild conditions in terms of the information potential. We consider the case that the input data points are randomly perturbed, i.e. $y_i = x_i + \epsilon p_i$, for $i \in [1, n]$, where $p_i$ is comprised of i.i.d. random variables. Let $\{\lambda_i\}_{i=1}^n$, $\{\mu_i\}_{i=1}^n$ denote the eigenvalues of normalized kernel matrices constructed from $\{x_i\}_{i=1}^n$ and $\{y_i\}_{i=1}^n$ respectively. We test the following noise distributions: Standard Gaussian $N(0, 1)$, Uniform $U(-\sqrt{3}, \sqrt{3})$, Student-t $t(3)/\sqrt{3}$ and Rademacher $\{\pm 1\}$ with $n = 100$ (detailed settings are given in the appendix). The examples of variation in eigenvalues ($\mu_i - \lambda_i$) and the standard deviation (multiplied by $n$) of entropy values after 100 trials are reported in Figure 3. It verifies our analysis that when $\epsilon$ is small, the eigenvalues $\mu_i$ are nearly independently perturbed. Moreover, our low-rank definition achieves lower variance than matrix-based Rényi’s entropy under different choices of $\alpha$, in which smaller $k$ corresponds to higher robustness.

**Real Data Examples**

In this section, we demonstrate the great potential of applying our low-rank Rényi’s entropy functional and its multivariate extensions in two representative real-world information-related applications, which utilize the mutual information (information bottleneck) and multivariate mutual information (feature selection) respectively.

Application to Information Bottleneck

The Information Bottleneck (IB) methods recently achieve great success in compressing redundant or irrelevant information in the inputs and preventing overfitting in deep neural networks. Formally, given network input $X$ and target label $Y$, the IB approach tries to extract a compressed intermediate representation $Z$ from $X$ that maintains minimal yet meaningful information to predict the task $Y$ by optimizing the following IB Lagrangian:

$$\mathcal{L}_{IB} = I(Y, Z) - \beta \cdot I(X, Z),$$

where $\beta$ is the hyper-parameter that balances the trade-off between sufficiency (predictive performance of $Z$ on task $Y$, quantified by $I(Y, Z)$) and minimality (the complexity of $Z$, quantified by $I(X, Z)$). In practice, optimizing $I(Y, Z)$ is equivalent to the cross-entropy (CE) loss for classification tasks, so our target remains to optimize the latter term $I(X, Z)$. However, mutual information estimation is extremely hard or even intractable for high-dimension distributions, which is usually the case in deep learning. To address this issue, there have been efforts on using variational approximations to optimize a lower bound of $I(X, Z)$, e.g., Variational IB (VIB) (Alemi et al. 2017) and Nonlinear IB (NIB) (Kolchinsky, Tracey, and Wolpert 2019). We show that with low-rank Rényi’s entropy, $I(X, Z)$ can be directly optimized by approximating the largest $k$ eigenvalues of the kernel matrix $A$ constructed by $X$ and $Z$. Recall that the Lanczos method constructs an approximation $A \approx QTQ^\top$, where $Q \in \mathbb{R}^{n \times s}$ has orthogonal columns and $T \in \mathbb{R}^{s \times s}$ is tridiagonal, we have $\lambda_i = \lambda_i(Q^\top AQ)$ for all $i \in [1, s]$. Let $\sum_{i=1}^{s} \lambda_i u_i u_i^\top$ be the eigenvalue decomposition of $Q^\top AQ$, we can approximate the gradient of $S_k(\Lambda)$ as:

$$\frac{\partial S_k(\Lambda)}{\partial A} \approx \sum_{i=1}^{k} \frac{\partial S_k(\Lambda)}{\partial \lambda_i} \cdot Qu_i u_i^\top Q^\top.$$

In this experiment, we test the performance of matrix-based Rényi’s IB (MRIB) (Yu, Yu, and Principe 2021) and our low-rank variant (LRIB) with variational approximation-based objectives using VGG16 as the backbone and CIFAR10 as the classification task. All models are trained for 300 epochs with 100 batch size and 0.1 initial learning rate which is divided by 10 every 100 epochs. Following the settings in (Yu, Yu, and Principe 2021), we select $\alpha = 0.01$, $\beta = 0.01$, $k = 10$ and $s = 20$. The final results are reported in Table 1. It can be seen that the matrix-based approaches MRIB and LRIB outperform other methods, while our LRIB achieves the highest performance with significantly less training time.

Application to Feature Selection

In practical regression or classification machine learning tasks, many features can be completely irrelevant to the learning target or redundant in the context of others. Given a set of features $S = \{X_1, \cdots, X_L\}$ and the target label $Y$, we aim to find a subset $S_{\text{sub}} \subset S$ which leverage the expressiveness and the complexity simultaneously. In the field of information theoretic learning, this target is equivalent to maximizing the multivariate mutual information $I(S_{\text{sub}}; Y)$, which is computationally prohibitive due to the curse of high dimensionality. As a result, there have been tremendous efforts on approximation techniques that retain only the first or second order interactions and build mutual information estimators upon low-dimensional probability distributions, including Mutual Information-based Feature Selection (MIFS) (R. Battiti 1994), First-Order Util-
our definition enables higher robustness to noises in the data. Compared to the original matrix-based Rényi’s entropy, our definition enables higher robustness to noises in the data. This demonstrates the great potential of our low-rank Rényi’s entropy can be efficiently approximated by the fast Johnson–Lindenstrauss transform and approximate nearest neighbors.

Table 2: Information theoretic feature selection methods and their average rank over different feature sets in each dataset. The first and second best performances are marked as bold and underlined respectively.

Table 3: Number of instances (#I), features (#F), classes (#C) and discreteness of classification datasets used in feature selection experiments, running time comparison (minutes) of MRMI (left) and LRMI (right), and speedup ratios.

Conclusion

In this paper, we investigate an alternative entropy measure built upon the largest $k$ eigenvalues of the data kernel matrix. Compared to the original matrix-based Rényi’s entropy, our definition enables higher robustness to noises in the data and sensitivity to informative changes in eigenspectrum distribution with a proper choice of hyper-parameter $k$. Moreover, low-rank Rényi’s entropy can be efficiently approximated with $O(n{s}^2)$ random projection and $O(n^3)$ Lanczos iteration techniques, substantially lower than the $O(n^3)$ complexity required to compute matrix-based Rényi’s entropy. We conduct large-scale simulation and real-world experiments on information bottleneck and feature selection tasks to validate the effectiveness of low-rank Rényi’s entropy, demonstrating elegant performance with significant improvements in computational efficiency.
