Introduction

We developed novel variational MMAP inference algorithms and proximal convergent solvers, where we can improve the approximation accuracy while better preserving the original MMAP query by designing such a dual variational objective function that an upper bound approximation is applied only to the entropy of decision variables. A task of marginal-MAP (MMAP) inference is a “mixed” problem, where “max” or B-variables are decision variables to be optimized while all other variables are “sum” variables to be marginalized out. Since MMAP inference is computationally intractable (NP-complete), approximate variational inference techniques such as upper bounding or convex relaxations methods are of particular interest. To address the scalability issues of solving MMAP problems on complex loopy graphs with multi-variable factors, the community has been making significant progress in developing approximate variational algorithms. Unfortunately, most current approximation approaches for MMAP have focused on pair-wise models and their extensions to the models with high-order interactions often result in simplification of the original MMAP query and greater approximation errors.

We propose four novel contributions. (1) Our novel BEJG objective function for models with high-order interactions decomposes the intractable MMAP problem into a linear combination of tractable sub-problems and ensures that B-variables are maximized jointly within each sub-problem. This design ensures that all and only B-variables remain in our upper bound of the intractable entropy of B-variables (B-entropy), which is completely removed now from the joint entropy as required by the original MMAP query. (2) Our novel BEJG variational algorithms (generalized and zero-temperature) solve MMAP exactly on any junction graph of high-order interactions: (3) Additionally, we scale our variational approach to solve POMDP problems and show that we can find the optimal controller by MMAP inference in a single-DBN generative model of a special cascading structure. We are the first to our knowledge who proposed BEJG variational algorithms and proximal algorithms to solve MMAP on the models with high-order interactions.

BEJG Variational Approach for MMAP

Consider an equivalent junction graph (JG) representation of a Bayesian Network $G = (C, S, E)$ with clusters $C$, separators $S (S_{kl} \subseteq \{C_k \cap C_l\})$ and edges $E$. We ensure that this JG satisfies the running intersection property and family preservation property. We introduce types of clusters and separators by the type of variables in their scope (A and/or B-variables): $C = \{C^A \cup C^B \cup C^{AB}\}$ and $E = \{E^A \cup E^B \cup E^{AB}\}$. Each cluster potential $\psi_{C_k}(x)$ equals to the product of factors associated with this cluster. We use the form of the original joint distribution factorized via cluster potentials $\psi_{C_k}(x)$, which we generalize by including “dummy” separator functions $b_{S_{kl}} = 1, \forall k l \in E$. We also introduce parameters $\theta_{C_k}(x) = \ln \psi_{C_k}(x)$, $\theta_{S_{kl}}(x) = \ln b_{S_{kl}}(x)$ to obtain the convex exponential form:

$$p(x) = \exp[\sum_{k \in C} \theta_{C_k}(x) - \sum_{kl \in E} \theta_{S_{kl}}(x)] .$$

We derive our novel BEJG variational approximation for MMAP by (1) representing the MMAP problem with its exact dual variational form (Liu and Ihler 2013), and (2) designing a tractable BEJG objective function with a special upper bound approximation for B-entropy, which is a linear combination of all AB, B cluster and separator entropies with B-variables only.

**Theorem 1** The optimization of BEJG free energy $E_{BEJG}^{MMAP}$ over the marginals from a convex set $L$ provides an accurate MMAP estimate on general junction graphs with high-order interactions:

$$\max_{\tau \in L} F_{BEJG}^{MMAP} = \mathbb{E}_{\tau}[\theta(x)] + \sum_{kl \in E^{AB}} H_{S_{kl}}(x^{B;}\tau) + \sum_{k \in C \setminus C^A} H_{C_k}(\tau) - \sum_{kl \in E^B} H_{S_{kl}}(\tau) - \sum_{k \in C} H_{C_k}(x^{B;}\tau)$$

(1)
where set of locally consistent marginals $L := \{\tau : \tau \geq 0; \sum_{x_{sk_l}} \tau_{C_k}(x) = \tau_{S_{sk_l}}(x), \forall kl\}$: the expected energy via cluster and separator marginals is $\mathbb{E}_\theta[\gamma(x)] = \sum_{k \in C} \sum_{x_{sk_l}} \tau_{C_k}(x) \cdot \theta_{C_k}(x) - \sum_{kl \in E} \sum_{x_{sk_l}} \tau_{S_{sk_l}}(x) \cdot \theta_{S_{sk_l}}(x)$. $H_{C_k}(\tau) = -\sum_{x_{sk_l}} \tau_{C_k}(x) \ln \tau_{C_k}(x)$ is a cluster entropy via cluster marginals; $H_{S_{sk_l}}(\tau) = -\sum_{x \in S_{sk_l}} \tau_{S_{sk_l}}(x) \ln \tau_{S_{sk_l}}(x)$ is a separator entropy.

We also provide special conditions when our BEJG approximation scheme gives exact MMAP solutions. Thus, we: (1) specify a special structure of a junction graph with high order interactions (denoted as AB-tree JG) on which MMAP inference is tractable, (2) prove that our BEJG objective function equals to the exact MMAP dual function on any AB-tree JG. Importantly, our BEJG objective function is distinct from JGBP approximate objective (Liu and Ihler 2013) since our special approximation for the B-conditional entropy $H(X_A | X_B, q)$ ensures that B-entropy is completely removed from the joint entropy as required by the exact MMAP dual form (Liu and Ihler 2013).

We designed generalized and zero-temperature BEJG variational algorithms for MMAP, which fixed points correspond to stationary points of BEJG variational problem (1).

**Algorithm 1 Zero-temperature BEJG algorithm**

for iteration $n = 1, 2, \ldots$ pass messages $\mu_{k \rightarrow l}(x_{sk_l})$ from a cluster $C_k$ to a cluster $C_l$, $\forall kl \in E$:

$$C_k \rightarrow C_l: \mu_{k \rightarrow l}(x_{sk_l}) = \sum_{x_{sk_l}} \alpha(x_{sk_l})$$  \hspace{1cm} (2)

, where $\alpha(x_{sk_l}) := \frac{\psi_{C_l}(x_{sk_l})}{\sum_{x_{sk_l}} \psi_{C_l}(x_{sk_l})} \prod_{j \in N(k) \setminus l} \mu_{j \rightarrow k}(x_{sk_l})$

$$C_k^{AB} \rightarrow C_l: \mu_{k \rightarrow l}(x_{sk_l}) = \max_{x_{sk_l}} \left\{ \sum_{x_{sk_l}} \alpha(x_{sk_l}) \right\}$$

$$C_k^{AB} \rightarrow C_l: \mu_{k \rightarrow l}(x_{sk_l}) = \sum_{x_{sk_l}} \left\{ \alpha(x_{sk_l}) \right\} \cdot \delta[x_{sk_l}]$$

, where $\delta$ is the indicator function, s.t. $\delta = 1$ if $x_{sk_l} = x_{sk_l}^*$ and $\delta = 0$ otherwise, $\forall x_{sk_l}^* \in X_{sk_l}^*$; and local MMAP is:

$$X_{sk_l}^* = \arg\max_{x_{sk_l}} \sum_{x_\delta} \psi_{C_l}(x) \prod_{j \in N(k)} \mu_{j \rightarrow k}(x_{sk_l})$$

$$C_k^{AB} \rightarrow C_l: \mu_{k \rightarrow l}(x_{sk_l}) = \max_{x_{sk_l}} \beta(x_{sk_l}) \cdot \sum_{x_{sk_l}} \alpha(x_{sk_l})$$

, where $\beta(x_{sk_l}) = \sum_{x_{sk_l}^*} \psi_{C_l}(x) \prod_{j \in N(k) \setminus l} \mu_{j \rightarrow k}(x_{sk_l})$

At convergence, decode optimal MMAP configurations $X_{sk_l}^*$ with a Trace-MMAP procedure

**Results.** We compare our variational and proximal algorithms to existing variational methods, including JGBP (Liu and Ihler 2013), Weighted mini-bucket (Dechter and Rish 2003), and Dual decomposition (Pang, Liu, and Ihler 2015) methods. Here, we use (1) simulated models of various complexity generated from synthetic distributions, (2) Bayesian networks from known UAI benchmarks, and (3) MMAP problems encoding non-pairwise sequential decision-making problems. We show that our solvers outperform other variational methods for many of reported cases (cf. Table 1 and appendix). Additionally, we demonstrate the important real-life application of the proposed variational approaches to solve complex tasks of policy optimization and sequential decision-making problems (complex MMAP instances) (Kiselev and Poupart 2014), (Kiselev 2018).
