Abstract

Pseudo-Boolean solvers hold out the theoretical potential of exponential improvements over conflict-driven clause learning (CDCL) SAT solvers, but in practice perform very poorly if the input is given in the standard conjunctive normal form (CNF) format. We present a technique to remedy this problem by recovering cardinality constraints from CNF on the fly during search. This is done by collecting potential building blocks of cardinality constraints during propagation and combining these blocks during conflict analysis. Our implementation has a non-negligible but manageable overhead when detection is not successful, and yields significant gains for some SAT competition and crafted benchmarks for which pseudo-Boolean reasoning is stronger than CDCL. It also boosts performance for some native pseudo-Boolean formulas where this approach helps to improve learned constraints.

1   Introduction

The Boolean satisfiability problem (SAT) is one of the most formidable challenges—and impressive success stories—of computer science. Although SAT is an NP-complete problem (Cook 1971; Levin 1973), and is widely believed to be exponentially hard in the worst case, the last few decades have witnessed the emergence of highly efficient SAT solvers based on *conflict-driven clause learning (CDCL)* (Marques-Silva and Sakallah 1999),[1] with further improvements in (Moskewicz et al. 2001) and later papers. Today, these solvers are routinely used to solve large-scale real-world problems in a wide range of application areas (see (Biere et al. 2009) for a comprehensive reference).

One shortcoming of CDCL is that it uses a fairly weak method of reasoning—namely *resolution*, for which exponential lower bounds are known even for simple combinatorial principles (Haken 1985; Urquhart 1987). Another weakness is that the input must be encoded in conjunctive normal form (CNF), which deprives the solver of the possibility to reason with more expressive higher-level constraints.

A natural strengthening of CNF is to allow *pseudo-Boolean (PB) constraints*, i.e., integral linear inequalities

[1]A similar idea in the context of CSPs was independently developed in (Bayardo Jr. and Schrag 1997).

over Boolean variables, which gives a succinct way of encoding problems in many domains. CDCL solvers can then be applied to such problems by translating the input to CNF (as in, e.g., *MiniSat+* (Eén and Sörensson 2006), *Open-WBO* (Martins, Manquinho, and Lynce 2014), and *NaPS* (Sakai and Nabeshima 2015)) or by keeping the pseudo-Boolean input but deriving new constraints in the form of disjunctive clauses (as in methods implemented in *clasp* (Gebser, Kaufmann, and Schaub 2012) and the *Sat4j* library (Le Berre and Parrain 2010)). Another approach, which is quite attractive from a theoretical point of view, is to go beyond resolution and try to harness the power of *cutting planes* (Cook, Coullard, and Turán 1987). The conflict-driven paradigm has been extended to this setting in pseudo-Boolean solvers like *PRS* (Dixon and Ginsberg 2002), *Galena* (Chai and Kuehlmann 2005), *Pueblo* (Sheini and Sakallah 2006), *Sat4j* (Le Berre and Parrain 2010), and *RoundingSat* (Elffers and Nordström 2018).

A critical flaw of current cutting-planes-based solvers, however, is that while this method of reasoning is exponentially more powerful than resolution in theory, and does not care much about whether the input is presented in CNF or pseudo-Boolean form, the algorithms actually used in implementations of such solvers make them collapse to CDCL as soon as the input is given in CNF (Hooker 1988; 1992; Vinyals et al. 2018). This is clearly a highly unsatisfactory state of affairs—all the more so since a user of the solver might not be aware of that a problem can be rewritten more efficiently using pseudo-Boolean constraints, or that such low-level details of the syntactic representation can make an exponential difference in performance.

Our goal is to address this problem in a principled way, by rewriting CNF when a more efficient representation is possible, while maintaining good overall performance when no obvious improvement can be made. More concretely, in this work we propose a way of recovering *cardinality constraints*, saying that at most k variables (or at least k variables) in some subset can be true, from CNF. Cardinality constraints are already enough to make pseudo-Boolean reasoning exponentially stronger than resolution, and have been argued to capture most of the improvement over CDCL in practice (Chai and Kuehlmann 2005).

Earlier work on recovering cardinality constraints, which we will refer to as *cardinality detection*, was done in (Ansótegui 2004; Ansótegui et al. 2007). Some SAT solvers in the SAT competition also include recovery of cardinality constraints in the preprocessing phase (Biere 2013), though in these solvers the cardinality constraints are only used in a variable elimination algorithm to check for unsatisfiability during preprocessing. To the best of our knowledge, the only previous systematic investigation of cardinality detection in the context of pseudo-Boolean reasoning is (Biere et al. 2014). There, two types of detection were proposed: syntactic and semantic. They are both performed during a preprocessing step, and the recovered cardinality constraints are added to the formula before starting the pseudo-Boolean search. The general idea is to discover building blocks in the form of short clauses, and then extend them as far as possible to larger cardinality constraints. As an example, consider the at-most-1 constraint $x_1 + x_2 + x_3 + x_4 \leq 1$, which can be encoded in CNF as $S = \{\overline{x}_1 \vee \overline{x}_2, \overline{x}_1 \vee \overline{x}_3, \overline{x}_1 \vee \overline{x}_4, \overline{x}_2 \vee \overline{x}_3, \overline{x}_2 \vee \overline{x}_4, \overline{x}_3 \vee \overline{x}_4\}$. Cardinality detection starts from a single clause, say, $x_1 + x_2 \leq 1$ (which is the PB representation of $\overline{x}_1 \vee \overline{x}_2$), extends this constraint by adding x_3 after detecting the clauses $\{\overline{x}_1 \vee \overline{x}_3, \overline{x}_2 \vee \overline{x}_3\}$, and then also adds x_4 after finding the remaining clauses in S. In syntactic cardinality detection, the building blocks are found by syntactic checks of the input formula. In the semantic approach they are found by *probing*, i.e., assigning a variable and studying what other assignments are propagated. For example, to detect all binary clauses containing $\overline{x}_1$, one sets x_1 to true and collects literals ℓ propagated to false—for all such literals we have a building block $\overline{x}_1 \vee \overline{\ell}$ that could be part of an at-most-1 constraint. For $k > 1$ one can set k-tuples of literals $\{\ell_1, \ldots, \ell_k\}$ to true and gather building blocks $\overline{\ell}_1 \vee \ldots \vee \overline{\ell}_k \vee \overline{\ell'}$ for every literal ℓ' propagated to false.

1.1 Our Contribution

Our approach differs from (Biere et al. 2014) in several key aspects. We do not perform cardinality detection during a separate preprocessing step, but continuously during the solver execution. We have no syntactic detection, which is the main focus of (Biere et al. 2014), but instead use a semantic technique. However, we do not use dedicated probing, which quickly becomes too inefficient as k grows. Instead, we analyze the directed acyclic graph of unit propagations constructed during the "forward phase" of the solver search algorithm, and find clauses by considering cuts in this graph. During the "backward phase" of conflict analysis, we check on-the-fly if the short clauses involved in the conflict can be strengthened to cardinality constraints using previously detected building blocks. Importantly, these modifications allow us to recover at-most-k constraints not only for $k \in \{1, 2\}$ as in (Biere et al. 2014) but also for larger k.

Furthermore, the fact that cardinality detection is performed throughout the search means that the solver can also discover and exploit cardinality constraints that were not there in the original input, but have arisen as a result of the constraints learned during search. Recovery of short clauses during CDCL search has been considered before (Han, Jin,

and Somenzi 2011; Heule, Järvisalo, and Biere 2013). However, our work differs from these papers in that they detect only binary clauses whereas we find also longer (though still comparatively short) clauses, and in that we use the found clauses to form syntactic cardinality constraints.

We have implemented our cardinality detection algorithm inside the pseudo-Boolean solver *RoundingSat* (Elffers and Nordström 2018). Our main conclusion is that the overhead of our approach is not too high on average, while at the same time we are able to solve a number of formulas faster than other CDCL and PB solvers. In more detail, in the relevant decision track in the latest pseudo-Boolean competition our solver performs similarly to though somewhat worse than the baseline *RoundingSat* solver. On CNF formulas from the SAT competitions, CDCL solvers run much faster in general, as is to be expected. Nevertheless, there are a number of benchmarks where the extra effort of our approach pay off, and where our solver is the only solver that finishes within the time limit. Besides that, there are many examples of crafted benchmarks where the new cardinality detection solver is better than existing CDCL and pseudo-Boolean approaches, including the earlier mentioned PB solver with cardinality detection from (Biere et al. 2014). Interestingly, we have also found that cardinality detection improves performance dramatically for some pseudo-Boolean formulas which are very hard in practice for PB solvers such as *RoundingSat* although the encoding seems to be the most natural one and the solvers should be able to prove unsatisfiability very efficiently in principle. While our work certainly leaves room for further improvement, this suggests that on-the-fly cardinality detection could be a useful technique in improving pseudo-Boolean reasoning in general, in contrast to just recovering cardinality constraints encoded in an unhelpful manner as a set of clauses.

1.2 Organization of This Paper

After giving some very brief preliminaries in Section 2, we describe our method for cardinality detection in more detail in Section 3 and report results from experimental evaluations in Section 4. We end in Section 5 with a discussion of possible directions for future work.

2 Preliminaries

Throughout this paper we use the term *pseudo-Boolean (PB) constraint* to refer to a linear inequality $\sum_i a_i \ell_i \geq A$ or $\sum_i a_i \ell_i \leq A$, where a_i and A are integers and $\ell_i \in \{x_i, \overline{x}_i\}$ are positive or negative literals over Boolean variables related by $x_i + \overline{x}_i = 1$. This last equality can always be used to rewrite any PB constraint in so-called *normalized form* as a greater-than-or-equal constraint with all coefficients a_i non-negative, and so we can freely assume that this is the case in what follows. A *cardinality constraint* is a PB constraint with all $a_i \in \{0, 1\}$, where an *at-most-k constraint* is of the form $\sum_i \ell_i \leq k$ and an *at-least-k constraint* looks like $\sum_i \ell_i \geq k$. Semantically speaking, a disjunctive clause $D = \ell_1 \vee \cdots \vee \ell_w$ is exactly the same as an at-least-1 constraint $\ell_1 + \cdots + \ell_w \geq 1$, and so we identify the two. We can also view D as a set of literals, and say that D is a *subclause* of D' if $D \subseteq D'$ viewed as sets. We note that any

pseudo-Boolean constraint $\sum_i a_i \ell_i \geq A$ with a_i, A positive can be *rounded* to a clause $\sum_i \ell_i \geq 1$ that is implied by the constraint.

Due to limited space we cannot go into too much detail regarding conflict-driven pseudo-Boolean solving, but here follows a condensed description of the notions that we will need. At all times, the solver maintains an ordered *trail* of literals ℓ assigned to true, where every assignment is either a free *decision* or a *unit propagation* caused by some PB constraint C that would be violated if ℓ were to be set to false; such a C is referred to as a *reason* for ℓ. The solver alternates between making decisions and exhaustively inferring all unit propagations that follow from each such decision until either a satisfying assignment is found or a *conflict* is reached in the form of a violated constraint. In the latter case, the solver switches to *conflict analysis*. Here the solver combines the conflicting constraint with the reason constraints responsible for the propagations falsifying it one by one in reverse chronological order using the so-called *resolution rule*, after first *reducing* every reason constraint to suitable form (this reduction step is the main difference between PB solving and CDCL). The conflict analysis ends when an *assertive* constraint has been derived that will automatically flip some literal assignment when the solver backtracks.

Typically, the solver spends the vast majority of its time on unit propagation, and so achieving fast propagation is crucial for good performance. Another interesting measure is the number of conflicts reached before the solver terminates, which can be viewed as an indicator of the quality of the search. We refer the reader to the survey chapter (Buss and Nordström 2020) for a more in-depth comparison of CDCL and pseudo-Boolean solving.

3 Cardinality Detection Method

As explained above, our cardinality detection algorithm consists of two phases. During the solver "forward phase" of decisions and unit propagation we derive short clauses, which we call *building blocks*, that could potentially be used to form cardinality constraints. During the "backward phase" of conflict analysis we try to obtain cardinality constraints from these building blocks. The second phase is fairly standard, but the first phase, and how everything fits together, is novel. In this section, we describe all of this in more detail and give some illustrating examples.

3.1 Finding Cardinality Building Block Clauses

As a motivating example, consider again the at-most-1 constraint $x_1 + x_2 + x_3 + x_4 \leq 1$, encoded in clausal form as $\{\overline{x}_i \vee \overline{x}_j \mid 1 \leq i < j \leq 4\}$. In order to recover this cardinality constraint, we need to detect the clausal building blocks. If, say, $\overline{x}_1 \vee \overline{x}_2$ is not part of the the original formula syntactically, then we would hope that the solver would detect the implication $x_1 \rightarrow \overline{x}_2$ or $x_2 \rightarrow \overline{x}_1$ during unit propagation. However, such an implication might be indirect: it could be that x_1 implies y and z through the clauses $\overline{x}_1 \vee y$ and $\overline{x}_1 \vee z$, which in turn imply $\overline{x}_2$ through the clause $\overline{y} \vee \overline{z} \vee \overline{x}_2$. The solver needs to be able to discover also such indirect implications.

The sequence of decisions and unit propagations a solver makes during search can be described by a directed *implication graph*, where there is a vertex for every literal assigned to true, and for a propagated literal this vertex has incoming edges from the negations of all other literals in the clause that propagated it (these negated literals have also been set to true, since the clause is propagating, and so there are vertices for them in the graph). In our example, we could read off from the implication graph that it is sound to derive $\overline{x}_1 \vee \overline{x}_2$. This is so since every path to $\overline{x}_2$ in the implication graph goes through x_1, and hence setting x_1 to true is sufficient to propagate x_2 to false. In general, for every set of literals L such that all paths from decisions to a literal p go through a vertex in L, we have the implication $(\bigwedge_{\ell \in L} \ell) \rightarrow p$, or in clausal form $\bigvee_{\ell \in L} \overline{\ell} \vee p$. We refer to such a set L as a *cut*, and the building blocks that our algorithm derives are clauses corresponding to such cuts.

Importantly, we do not collect all cuts and clauses that can be obtained from them, but only one cut and clause for each propagated literal. The intuition is that this clause should essentially contain the decisions directly responsible for propagating the literal plus the literal itself.

In more detail, our cut generation algorithm for deriving clausal building blocks takes a parameter $w_{\max}$ specifying the maximum width of clauses to detect. For example, if $w_{\max} = 2$, then only binary clauses are derived, which only suffices to form at-most-1 constraints. The idea is that during the search the solver should find such clauses for propagated literals by computing a cut containing the decisions that have a path to this literal in the implication graph and adding the clause encoding that this cut implies the propagated literal as described above. We need a slight adjustment of this, however, in that in addition to decisions literals we also include in the cut propagated literals for which the already computed cuts hit the $w_{\max}$ size bound. See Algorithm 1 for the pseudocode, where $cut[p]$, if defined, contains a (recursively computed) cut of size less than $w_{\max}$ for the literal p in the implication graph. In Algorithm 1, the *roundToClause* method reduces the pseudo-Boolean reason constraint $\sum_i a_i \ell_i \geq A$ for literal p to a clause $\sum_i \ell_i \geq 1$ (possibly after first having weakened the constraint by removing some literals, so that the rounded clause is still propagating). Next, the decision cut for p is constructed. For each literal ℓ in the reason clause, if ℓ has a decision cut already calculated, we add the set of decisions responsible for propagating it to the cut for p. Otherwise, we add ℓ itself.

3.2 Filtering Building Block Clauses

A first naive approach would be to add all found building block clauses to the constraint database and let the solver use all of them for propagation and conflict analysis. This turns out not to be a good idea, however: it slows down the search speed, and also significantly worsens search quality measured in total number of conflicts. One way to decrease the number of clauses is to compute cuts for all literals during propagation, but only add the corresponding clauses for literals that actually take part in the conflict analysis during the backward phase. Furthermore, for such clauses we

Data: Propagated literal p; max width $w_{\max}$ of clauses
Result: A cut for p of size at most $w_{\max} - 1$
if *p was propagated by constraint C_{reason}* **then**
   $C \leftarrow \text{roundToClause}(C_{reason}, p)$
   $cut[p] \leftarrow \emptyset$
   foreach $\bar{\ell} \in C \setminus \{p\}$ **do**
      if $cut[\ell] \neq \text{UNDEFINED}$ **then**
         $cut[p] \leftarrow cut[p] \cup cut[\ell]$
      else
         $cut[p] \leftarrow cut[p] \cup \{\ell\}$
      end
   end
end
if $|cut[p]| > w_{\max} - 1$ **then** $cut[p] \leftarrow \text{UNDEFINED}$
Algorithm 1: Algorithm for deriving building blocks.

while C_{confl} *is not assertive* **do**
   $\ell \leftarrow$ literal assigned last on the trail ρ
   if $\bar{\ell}$ *occurs in* C_{confl} **then**
      $C_{\text{reason}} \leftarrow \text{reason}(\ell, \rho)$
      $C_{\text{reason}} \leftarrow \text{reduceReason}(C_{\text{reason}}, \ell, \rho)$
      if C_{reason} *is clause of size* $\leq w_{\max}$ **then**
         $C_{\text{reason}} \leftarrow \text{cardDetect}(C_{\text{reason}})$
      end
      $C_{\text{confl}} \leftarrow \text{resolve}(C_{\text{confl}}, C_{\text{reason}}, \bar{\ell})$
   end
   $\rho \leftarrow \text{removeLast}(\rho)$
end
return C_{confl}
Algorithm 2: Conflict analysis with cardinality detection.

also apply a filtering step, and send clauses not passing this filter to a separate storage of inactive constraints that do not take part in the search (i.e., the solver does not consider such clauses when performing unit propagation).

Our filter accepts only building blocks C that are *part of an at-least-2 constraint*, by which we mean that there is some literal $\ell \notin C$ such that for all literals $\ell_0 \in C$ the clause $(C \setminus \{\ell_0\}) \cup \{\ell\}$ can be found in storage. This is perhaps best illustrated by an example. Suppose that building blocks $C_1 = x_1 \lor x_2 \lor x_4$, $C_2 = x_1 \lor x_3 \lor x_4$, and $C_3 = x_2 \lor x_3 \lor x_4$ have previously been detected. Then if the clause $C_4 = x_1 \lor x_2 \lor x_3$ is added, we see that all clauses $(C_4 \setminus \{x_i\}) \cup \{x_4\}$ for $i = 1, 2, 3$ are is in storage, and these clauses together with C_4 imply the constraint $x_1 + x_2 + x_3 + x_4 \geq 2$. Hence, the filter accepts C_4 (and also retroactively C_1, C_2, and C_3).

A more generous criterion for being part of an at-least-2 constraint could have been that all clauses $(C \setminus \{\ell_0\}) \cup \{\ell\}$ *or subclauses thereof* could be found (in our example, that $x_1 \lor x_2 \lor x_4$ and $x_3 \lor x_4$ were present, say). However, we have found that using such a filter degrades performance substantially on certain benchmarks.

3.3 Forming Cardinality Constraints

The actual construction of cardinality constraints happens during the backward phase while the solver is analysing the conflict it just reached. When a short clause appears as the reason in the conflict analysis, the solver attempts on the fly to extend this clause to a largest possible cardinality constraint. As described in the introduction, this is done by a greedy algorithm that considers variables in decreasing order of activity in recent conflicts (in more technical terms, variables with higher scores as measured by the *variable state independent decaying sum (VSIDS)* (Moskewicz et al. 2001) are tried first). We have also attempted to use heuristics based on the activity of building block clauses in conflict analysis, as well as other non-adaptive heuristics, but have found that the approach based on variable acticity worked best.

This recovery of cardinality constraints is integrated in the pseudo-Boolean conflict analysis as described in Algo-

rithm 2. In this algorithm, we resolve the conflicting constraints with reason constraints for the propagations falsifying it until the derived constraint is such that it will flip the value assigned to some literal before the last decision was made. As mentioned in Section 2, an extra step in PB conflict analysis compared to CDCL is that the reason constraints need to be reduced in order for the algorithm to work. What we add further to do on-the-fly cardinality detection is the *cardDetect* function, which recovers cardinality constraints from building block clauses as has been described above.

One important difference from the limited cardinality constraint detection during the filtering step, however, is that during cardinality constraint recovery we do not require exact syntactic matches of clauses taking part in cardinality constraints, but also look for subclauses of such clauses. The reason for this is that it might well happen that a cardinality constraint is formed by stronger clauses than those in its canonical encoding to CNF. All short clauses participate in forming cardinality constraints, including building block clauses in inactive storage that have not yet passed our filtering test.

3.4 A Worked-out Toy Example

Let us now show how our PB solver with cardinality detection can efficiently solve a pseudo-Boolean formula with some clausal constraints. We consider a toy formula encoding the contradictory constraints $x_1 + x_2 + x_3 + x_4 \geq 3$ and $x_1 + x_2 + x_3 + x_4 \leq 2$, but with the second constraint obfuscated as a set of clauses with extra variables added as in Figure 1. Note that the last two constraints $\bar{x}_1 + \bar{x}_3 + \bar{x}_4 \geq 1$ and $\bar{x}_2 + \bar{x}_3 + \bar{x}_4 \geq 1$ are just the pseudo-Boolean representations of the clauses $\bar{x}_1 \lor \bar{x}_3 \lor \bar{x}_4$ and $\bar{x}_2 \lor \bar{x}_3 \lor \bar{x}_4$, which are the building blocks we are expecting for the at-most-2 constraint.

Suppose that the solver decides to set x_2 true and then x_1 true. Then the two top right constraints propagate y_1 to true and then x_3 to false as shown in the implication graph in Figure 2 (where we also show the propagating constraints in clausal form to make the illustration easier to follow). Also, the three bottom left constraints in Figure 1 propagate z_1 and z_2 to true, which in turn propagates x_4 to false as shown in the implication graph in Figure 3. From cuts in these im-

$$x_1 + x_2 + x_3 + x_4 \geq 3 \qquad\qquad \overline{x}_1 + y_1 \geq 1$$
$$\overline{x}_2 + \overline{z}_1 + z_2 \geq 1 \qquad \overline{x}_2 + \overline{y}_1 + \overline{x}_3 \geq 1$$
$$\overline{x}_1 + z_1 \geq 1 \qquad\qquad \overline{x}_1 + \overline{x}_3 + \overline{x}_4 \geq 1$$
$$\overline{z}_2 + \overline{x}_4 \geq 1 \qquad\qquad \overline{x}_2 + \overline{x}_3 + \overline{x}_4 \geq 1$$
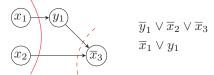

Figure 1: Toy pseudo-Boolean formula.

$$\overline{y}_1 \vee \overline{x}_2 \vee \overline{x}_3$$
$$\overline{x}_1 \vee y_1$$

Figure 2: Implication graph for detection of $\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3$.

plication graphs the solver can derive the clausal building blocks $\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3$ and $\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_4$, respectively.

A this point, the solver also discovers that the constraint $x_1 + x_2 + x_3 + x_4 \geq 3$ is falsified, and so we have a conflict. In the conflict analysis, if x_4 was propagated last, then the first reason constraint in reverse chronological order is the clause $\overline{x}_1 + \overline{x}_2 + \overline{x}_4 \geq 1$. When cardinality detection is applied on this clause, the solver finds that $\overline{x}_3$ can be added because all subclauses of length 3 of $\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3 \vee \overline{x}_4$ are present. Thus, the reason constraint is strengthened to $\overline{x}_1 + \overline{x}_2 + \overline{x}_3 + \overline{x}_4 \geq 2$ (which is just the constraint $x_1 + x_2 + x_3 + x_4 \leq 2$ written in normalized form). When the solver resolves the reason constraint $\overline{x}_1 + \overline{x}_2 + \overline{x}_3 + \overline{x}_4 \geq 2$ with the conflict constraint $x_1 + x_2 + x_3 + x_4 \geq 3$ by adding them together, all literal pairs x_i and $\overline{x}_i$ cancel leaving constants 1 and we are left with $5 \geq 2 + 3$, or after simplification $0 \geq 1$. This is a contradiction, and the solver immediately terminates and declares the instance unsatisfiable. Although we do not have space to discuss this here, it is straightforward to verify that PB conflict analysis without cardinality detection would instead derive the learned constraint $x_3 \geq 1$, i.e., the unit clayse x_3. This would cause the solver to backtrack to top level, undoing the decisions made on x_1 and x_2, and then propagate x_3 to true. After this, the solver would need to start over with new decisions and propagations, though.

4 Experimental Evaluation

We have implemented our approach within the pseudo-Boolean solver *RoundingSat* (Elffers and Nordström 2018). We refer to the solver with cardinality detection as *RoundingSat-Card*. We set $w_{\max} = 5$ in all experiments. In (Biere et al. 2014), the bound is set to $w_{\max} = 3$ (binary and ternary clauses), and this low value is necessary for their approach to run fast enough. We report results from two types of benchmarks: SAT and PB competitions from 2016–2018, and a number of crafted benchmarks. The motivation for including these crafted benchmarks is to make clear that the approach put forward in this paper has potential to solve formulas which earlier solvers could not deal

$$\overline{z}_2 \vee \overline{x}_4$$
$$\overline{x}_2 \vee \overline{z}_1 \vee z_2$$
$$\overline{x}_1 \vee z_1$$

Figure 3: Implication graph for detection of $\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_4$.

with. This is hard to see from the results in the competitions because the benchmarks in the competitions were selected to be challenging but not completely out of reach for existing solvers. This means that if some benchmarks critically required on-the-fly cardinality detection to be solved fast, then by design such formulas would have been likely to be omitted from the competition sets.

On CNF formulas, we compared our solver to *Sat4j Card* from (Biere et al. 2014) as well as to the state-of-the-art SAT solvers *CaDiCaL* (CaDiCaL 2019) and *Glucose* (Audemard and Simon 2009). On pseudo-Boolean (OPB) formulas, we again compared our solver to *Sat4j Card* and also to the state-of-the-art PB solvers *Sat4j* (Le Berre and Parrain 2010) and *clasp* (Gebser, Kaufmann, and Schaub 2012). *Sat4j* comes in one version *Sat4j Res* that only reasons with clauses, and another *Sat4j Res+CP* that runs in parallel the clause-based solver and a solver that reasons with general PB constraints. The solver *Sat4j CP* is too slow to run on its own in a competition setting. However, *Sat4j Card* uses only this solver plus cardinality detection. The experiments in (Biere et al. 2014) used also a different tool for cardinality detection, namely *Riss* (Manthey 2012). However, the solvers using *Riss* for preprocessing were found to do worse than what was reported in the paper, and therefore we discarded them.

For our experiments on SAT competition benchmarks we used a timeout of 5000 seconds. The results are as given in Figure 4. Here we see that *RoundingSat-Card* is not able to keep up with the fastest CNF SAT solvers, but that there exist benchmark families for which our cardinality detection turns out to be essential to solve the formula quickly. These families are, among others, synthesis of shortest straight-line programs (Fuhs and Schneider-Kamp 2010) and the $\text{GrandTour}^{\text{obs}}$ puzzle (Chowdhury, Müller, and You 2018). For the pseudo-Boolean competition 2016, using a timeout of 1800 seconds, *RoundingSat-Card* solves 1097 problems, compared to 1150 for *RoundingSat*, 1047 for *Sat4j Res+CP*, 665 for *Sat4j Card* and 963 for *clasp*. For this setting the cardinality detection is implemented efficiently enough for the solver to not slow down too much. The reason that *clasp* has a worse result is because some of these benchmarks are difficult for solvers reasoning with clauses, and easy for those reasoning with general PB constraints.

Let us next discuss our experiments on crafted benchmarks, starting with a number of variations on pigeonhole principle (PHP) formulas. First, we test cardinality detection on a number of encodings of standard PHP formulas (Biere et al. 2014). The results are given in Figure 5. We see that the solvers implementing cardinality detection perform significantly better than those that do not. Both pseudo-Boolean

solvers exhibit similar performance on these benchmarks.

Our second PHP-like formula is the two-pigeons-per-hole principle formula, which encodes the claim that $2n - 1$ pigeons do not fit into $n - 1$ holes if each hole has room for at most 2 pigeons. We use this benchmark to test detection of at-most-2 constraints. We consider four different encodings: the binomial encoding, which lists all building blocks in the input, and the three encodings of *MiniSat+* (Eén and Sörensson 2006): sorter networks, BDDs and adder networks. The reason that we use different encodings than in (Biere et al. 2014) is that the encodings used there are specifically for at-most-1 constraints. See Figure 6 for the results (except that the binomial encoding was so much easier than the other encodings for all solvers that we omit them). Here we see that *RoundingSat-Card* scales better than *Sat4j Card*, and also better than the best CDCL solvers.

We consider one more PHP-inspired formula. Here the needed building blocks are not already implied by unit propagation but have to be found through clause learning. These benchmarks are 3-colouring formulas generated by a reduction from the so-called graph functional pigeonhole principle. This reduction was proposed in the paper (Lauria and Nordström 2017).[2] The results are presented in Figure 7. Observe that *RSCard* scales reasonably well and much better than *RoundingSat* without cardinality detection, for which these formulas are exponentially hard. We wish to highlight two technical challenges when solving this formula. Firstly, typically multiple cardinality constraints can be detected, but only one choice works. It turns out that extending with variables in the order of VSIDS scores selects the right constraint. Secondly, adding all ternary clause building blocks degrades performance (in terms of number of reasoning steps, not only running time), but adding a filtering step

---

[2]A technical detail is that in order to solve these formulas using at-most-1 constraints we need to fix the colours of the "main gadget"—this corresponds to setting three variables to true (the formula can be solved by solving $3! = 6$ such subproblems).

Encoding	*Sat4j Card*	*RSCard*	*CaDiCaL*	*Glucose*
Sorter	4 (1504m)	12 (209m)	7 (1008m)	7 (1007m)

Adder	4 (1500m)	9 (701m)	6 (1167m)	6 (1168m)

Figure 6: Results for the two-pigeons-per-hole principle (13 benchmarks in total).

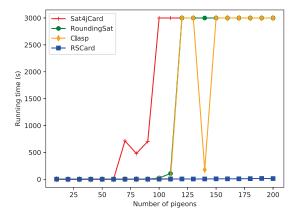

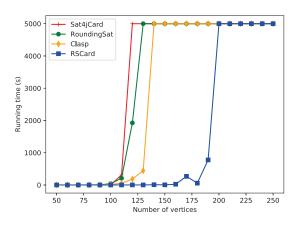

Figure 7: Results for 3-colouring formulas reduced from functional graph pigeonhole principle with left-degree 3.

for building blocks resolves this issue.

When comparing *RSCard* and *Sat4j Card* on pigeonhole principle-like problems, we note that probing can only recover clauses which were implied by unit propagation from the initial set of clauses. An encoding of a cardinality constraint into CNF is called *arc-consistent* if unit propagation on the set of clauses does not miss any propagations that one gets when running unit propagation on the cardinality constraint. For probing to find all building blocks of a cardinality constraint, the CNF encoding must be arc-consistent. This holds for all encodings of the pigeonhole principle in Figure 5. However, the sorter network and BDD encoding of the two pigeons per hole principle are also arc-consistent, but *Sat4j Card* does not perform well on these formulas. This indicates that a necessary condition for *Sat4j Card* to solve a formula efficiently is that all cardinality constraints the solver needs to run fast consist of clauses that are already implied by unit propagation by the initial set of clauses. From the results on the two pigeons per hole principle, we see that this is not a sufficient condition for *Sat4j Card* to recover the cardinality constraints.

Next, let us investigate a family of unsatisfiable benchmarks where the difficulty is not in finding the building blocks, but in combining them in the right way, because there are many possible overlapping cardinality constraints to find. These benchmarks encode the claim that a $(k - 1)$-colourable graph cannot contain a k-clique. This formula is easy for cutting planes, because a $(k - 1)$-colouring can be mapped to $(k - 1)$ at-most-1 constraints which when added to the clique constraint give a contradiction. However, every independent set in the graph is a possible at-most-1

Figure 8: Results for k-clique formulas on $(k-1)$-colourable graphs ($k = 25$).

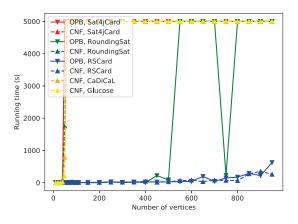

Figure 9: Results for even colouring formulas on random 4-regular graphs with a split edge.

constraint, so it is not clear how the solver would find $(k-1)$ such constraints that partition the graph. In our experiments, we set $k = 25$ and let the graph be a random $(k-1)$-colourable graph with each edge between differently coloured vertices present with probability $n^{-2/(k-1)}$. This is the probability where the transition between probably not containing a clique and probably containing a clique happens, if we ignore that the graph is $(k-1)$-colourable. From Figure 8 we can see that cardinality detection significantly improves the solving power of *RoundingSat*, though it still seems that it does not work well when n gets large.

We also would like to highlight one formula where cardinality detection pays off even though the formula as presented to the pseudo-Boolean solver is already easy in theory. The even colouring formula (Markström 2006) is an unsatisfiable benchmark where it seems that PB solvers have to combine addition and and division in the right way to run fast. This turns out to be very challenging for PB solvers

Encoding	*Sat4j Card*	*RSCard*	*RS*	*clasp*
CNF	10	10	2	1
OPB	10	10	10	1
recoverTree	1	10	2	2
recoverTreeReuse	1	10	2	2
recoverInput	1	6	2	2

Figure 10: Results for division-friendly formulas (10 benchmarks per family).

in practice, however. In slightly more details, the formula encodes that for a graph with all vertices having even degree but with an odd number of edges, it is not possible to colour edges black and white so that each vertex has the same number of black and white adjacent edges. See Figure 9 for experimental results on 4-regular random graphs with a split edge (to make the edge count odd). Quite interestingly, cardinality detection significantly improves performance of *RoundingSat* not only for the CNF encoding (where original *RoundingSat* has no chance) but also for the PB encoding.

Finally, let us discuss a set of benchmarks called division-friendly formulas (Gocht, Nordström, and Yehudayoff 2019), which are obfuscated versions of (otherwise extremely easy) subset cardinality formulas (Mikša and Nordström 2014). The encodings allow a PB solver implementing the division rule, such as *RoundingSat*, to solve the formulas efficiently in theory, but in practice these formulas are very hard for all pseudo-Boolean solvers. We see in Figure 10 that our solver with cardinality detection deals much more successfully with these obfuscated formulas, although it has difficulties with one specific encoding.

5   Conclusion and Future Work

In this paper we present a new approach to cardinality detection in pseudo-Boolean solvers that, in contrast to previous works such as (Biere et al. 2014), is not applied during preprocessing but throughout the execution of the solver, and is not based on probing or syntactic checks but extracts information semantically during search. Our experiments show that our approach incurs only a moderate overhead in the worst case, and sometimes yields dramatic improvements in efficiency. In particular, for formulas in CNF that encode cardinality constraints this technique allows pseudo-Boolean solvers to go beyond CDCL and harness the power of cutting-planes-based reasoning.

When running on CNF formulas, pseudo-Boolean reasoning is at a disadvantage to CDCL, because the data structures and algorithms required are more involved, and we cannot match the overall performance of state-of-the-art CDCL SAT solvers in a competition setting. However, our pseudo-Boolean solver enhanced with cardinality detection manages to solve some challenging benchmarks that are out of reach for existing CDCL and PB solvers. This shows that already our proof-of-concept implementation could play a useful role as a part of a portfolio SAT solver. Furthermore, even for some native pseudo-Boolean formulas, where there are no hidden PB constraints to detect, our experiments show

that adding on-the-fly cardinality detection can improve the pseudo-Boolean search and make the solver run faster.

As to future work, we believe that there is substantial room for improvements of our technique for cardinality detection. We would like to develop better heuristics for how to generate building block clauses from cuts in the implication graph and for which building blocks to keep or throw away. Another possible direction is to perform the cardinality detection in an adaptive fashion, where the solver would spend more or less time on detection depending on how much this work has paid off so far during search (provided that a meaningful way of measuring this could be found). We already know of crafted CNF formulas for which our approach does *not* work, although the formulas contain cardinality constraints (e.g., the so-called relativized pigeonhole principle (RPHP) formulas in (Atserias, Lauria, and Nordström 2016)), and as a first step would want to be able to solve also such formulas.

Another highly relevant challenge would be to detect cardinality constraints without going via the binomial encoding in our building block clauses. For example, an at-most-50-out-of-100 constraint is completely infeasible to detect with our current method, since the intermediate clausal representation becomes prohibitively large. However, if such a constraint were provided in the BDD encoding of *MiniSat+* (Eén and Sörensson 2006), then a procedure recognizing this encoding might be able to recover the constraint. Thus, we are suggesting to go back to a mix of semantic and syntactic detection techniques.

We would also like to extend the pseudo-Boolean detection to recover not only cardinalities but also more general linear inequalities where some of the coefficients are greater than 1, such as, e.g., $2x_1 + x_2 + x_3 + x_4 \geq 2$. So far we have not been able to implement detection and recovery of such constraints, since it would seem to require a redesign of the filtering method that we use to retain or throw away building blocks of cardinality constraints. Dropping the filter completely does not seem to be an option, as this ruins the effectiveness of the approach.

A final remark is that we have observed that probing sometimes beats our implication-graph-cut technique in finding useful building block clauses. However, if the decision heuristic of the solver is modified by setting the VSIDS decay factor to the fastest possible decay—meaning that when prioritizing variables to decide on the solver has very little memory and quickly forgets everything except the variables involved in the very latest conflicts—then our solver seems to be equally good as probing at finding the right building blocks. We would like to understand better the relationship between probing on the one hand and our implication-graph-cut technique combined with with fast VSIDS decay factor on the other.
