Abstract
In causal inference, all methods of model learning rely on testable implications, namely, properties of the joint distribution that are dictated by the model structure. These constraints, if not satisfied in the data, allow us to reject or modify the model. Most common methods of testing a linear structural equation model (SEM) rely on the likelihood ratio or chi-square test which simultaneously tests all of the restrictions implied by the model. Local constraints, on the other hand, offer increased power (Bollen 2013; McDonald 2002) and, in the case of failure, provide the modeler with insight for revising the model specification. One strategy of uncovering local constraints in linear SEMs is to search for overidentified path coefficients. While these overidentifying constraints are well known, no method has been given for systematically discovering them. In this paper, we extend the half-trek criterion of (Foygel, Draisma, and Drton 2012) to identify a larger set of structural coefficients and use it to systematically discover overidentifying constraints. Still open is the question of whether our algorithm is complete.

Introduction
Many researchers, particularly in economics, psychology, and the social sciences, use structural equation models (SEMs) to describe the causal and statistical relationships between a set of variables, predict the effects of interventions and policies, and to estimate parameters of interest. This qualitative causal information (i.e. exclusion and independence restrictions (Pearl 2009)), which can be encoded using a graph, imply a set of constraints on the probability distribution over the underlying variables. These constraints can be used to test the model and reject it when they are not consistent with data.

In the case of linear SEMs, the most common method of testing a model is a likelihood ratio or chi-square test that compares the covariance matrix implied by the model to that of the population covariance matrix (Bollen 1989; Shipley 1997). While this test simultaneously tests all of the restrictions implied by the model, failure does not provide the modeler with information about which aspect of the model needs to be revised. Additionally, if the model is very large and complex, it is possible that a global chi-square test will not reject the model even when a crucial testable implication is violated. In contrast, if the testable implications are enumerated and tested individually, the power of each test is greater than that of a global test (Bollen and Pearl 2013; McDonald 2002), and, in the case of failure, the researcher knows exactly which constraint was violated. Finally, in order to use the global chi-square test, it is necessary to know the degrees of freedom. For models where all of the free parameters are identifiable, the degrees of freedom is \( df = \frac{n(n-1)}{2} - n \) where \( p \) is the number of variables and \( n \) is the number of free parameters (Bollen 1989; Browne 1984). However, in cases where one or more free parameters are not identifiable (the model is underidentified), this equation no longer holds. Instead, the degrees of freedom is equivalent to the number of equality constraints on the covariance matrix. (See discussion on SEMNET forum with subject heading, “On Degrees of Freedom”.) Better understanding how to obtain and count these equality constraints provides insights into the validity of the global chi-square test.

There are a number of methods for discovering local equality constraints that can be applied to a linear structural equation model. It is well known that conditional independence relationships can be easily read from the causal graph using d-separation (Pearl 2009), and (Kang and Tian 2009) gave a procedure that enumerates a set of conditional independences that imply all others. Additionally, a tetrads is the difference in the product of pairs of covariances (e.g. \( \sigma_{12}\sigma_{34} - \sigma_{13}\sigma_{24} \)) and the structure of a linear SEM typically implies that some of the tetrads vanish while others do not (Bollen and Pearl 2013; Spearman 1904).

Overidentifying constraints, the subject of this paper, represent another strategy for obtaining local constraints in linear models. These constraints are obtained when there are at least two minimal sets of logically independent assumptions in the model that are sufficient for identifying a model coefficient, and the identified expressions for the coefficient are distinct functions of the covariance matrix (Pearl 2001; 2004). In this case, an equality constraint is obtained by
equating the two identified expressions for the coefficient$^{1,2}$. When this constraint holds in the data, the overidentified coefficient has the additional benefit of “robustness” (Pearl 2004). (Brito and Pearl 2002a) gave a sufficient condition for overidentification. Additionally, some of the non-independence constraints described by (McDonald 2002) are equivalent to overidentifying constraints. Finally, the Sargan test, also known as the Hansen or J-Test, relies on overidentification to check the validity of an instrumental variable (Sargan 1958; Hansen 1982). However, to our knowledge, no algorithm has been given for the systematic listing of overidentifying constraints. With this goal in mind, we modify the identifiability algorithm of (Foygel, Draisma, and Drton 2012) in order to discover and list overidentifying constraints.

It is well known that Wright’s rules allow us to equate the covariance of any two variables as a polynomial over the model parameters (Wright 1921). (Brito and Pearl 2002a) recognized that these polynomials are linear over a subset of the coefficients, thereby reducing the problem of identification to analysis of a system of linear equations and providing the basis for the “G-Criterion” of identifiability. (Brito and Pearl 2004) also noted that in some cases more linear equations could be obtained than needed for identification leading to the previously mentioned condition for overidentification. (Foygel, Draisma, and Drton 2012) generalized the G-Criterion, calling their condition the “half-trek criterion” and gave an algorithm that determines whether a SEM, as a whole, is identifiable. This algorithm can be modified in a straightforward manner to give the identified expressions for model coefficients. In this paper, we extend this (modified) half-trek algorithm to allow identification of possibly more coefficients in underidentified models (models where at least one coefficient is not identifiable)$^3$ and use it to list overidentifying constraints. These overidentifying constraints can then be used in conjunction with conditional independence constraints to test local aspects of the model’s structure. Additionally, they could potentially be incorporated into constraint-based causal discovery algorithms.

Related Work

In addition to the work discussed in the introduction, the identification problem has also been studied extensively by econometricians and social scientists (Fisher 1966; Bollen and Turkington 1990; Bekker, Merckens, and Wansbeek 1994; Rigdon 1995). More recently, the problem has been addressed by the AI community using graphical modeling techniques. The previously mentioned work by (Brito and Pearl 2002a; Brito and Pearl 2004; Foygel, Draisma, and Drton 2012) as well as (Brito and Pearl; 2002b) developed graphical criteria for identification based on Wright’s equations, while other work by (Tian 2005; 2007; 2009) used partial regression equations instead.

Non-conditional independence constraints have also been explored by the AI community in the context of non-parametric causal models. They were first noted by (Verma and Pearl 1990) while (Tian and Pearl 2002) and (Shpitser and Pearl 2008) developed algorithms for systematically discovering such constraints using the causal graph.

Preliminaries

We will use $\gamma_{YXZ}$ to represent the regression coefficient of $Y$ on $X$ given $Z$. Similarly, we will denote the covariance of $X$ on $Y$ given $Z$ as $\sigma_{YXZ}$. Throughout the paper, we also assume without loss of generality that model variables have been standardized to mean zero and variance one.

A linear structural equation model consists of a set of equations of the form,

$$x_i = pa_i^t\beta_i + \epsilon_i$$

where $pa_i$ (connoting parents) are the set of variables that directly determine the value of $X_i$, $\beta_i$ is a vector of coefficients that convey the strength of the causal relationships, and $\epsilon_i$ represents errors due to omitted or latent variables. We assume that $\epsilon_i$ is normally distributed.

We can also represent the equations in matrix form:

$$X = X^t\Lambda + \epsilon,$$

where $X = [x_1, \ldots, x_n]$, $\Lambda$ is a matrix containing the coefficients of the model with $\Lambda_{ij} = 0$ when $X_i$ is not a cause of $X_j$, and $\epsilon = [\epsilon_1, \epsilon_2, \ldots, \epsilon_n]^t$.

The causal graph or path diagram of an SEM is a graph, $G = (V, D, B)$, where $V$ are vertices, $D$ directed edges, and $B$ bidirected edges. The vertices represent model variables. Edges represent the direction of causality, and for each equation, $x_i = pa_i^t\beta_i + \epsilon_i$, edges are drawn from the variables in $pa_i$ to $x_i$. Each edge, therefore, is associated with a coefficient in the SEM, which we will often refer to as its path coefficient. The error terms, $\epsilon_i$, are not represented in the graph. However, a bidirected edge between two variables indicates that their corresponding error terms may be statistically dependent while the lack of a bidirected edge indicates that the error terms are independent.

If an edge, called $(X, Y)$, exists from $X$ to $Y$ then we say that $X$ is a parent of $Y$. The set of parents of $Y$ in a graph $G$ is denoted $Pa_G(Y)$. Additionally, we call $Y$ the head of $(X, Y)$ and $X$ the tail. The set of tails for a set of edges, $E$, is denoted $To(E)$ while the set of heads is denoted $He(E)$. If there exists a sequence of directed edges from $X$ to $Y$ then we say that $X$ is an ancestor of $Y$. The set of ancestors of $Y$ is denoted $An_G(Y)$. Finally, the set of nodes connected to $Y$ by a bidirected arc are called the siblings of $Y$ or $Sib_G(Y)$. In cases where the graph in question is obvious, we may omit the subscript $G$. 

---

$^1$Some authors use the term “overidentifying constraint” to describe any equality constraint implied by the model. We use it to describe only cases when a model coefficient is overidentified.

$^2$Parameters are often described as overidentified when they have “more than one solution” (MacCallum 1995) or are “determined from [the covariance matrix] in different ways” (Jöreskog et al. 1979). However, expressing a parameter in terms of the covariance matrix in more than one way does not necessarily mean that equating the two expressions actually constrains the covariance matrix. See (Pearl 2001) and (Pearl 2004) for additional explanation and examples.

$^3$Currently, state of the art SEM software like LISREL, EQS, and MPlus are unable to identify any coefficients in underidentified models.
A path from $X$ to $Y$ is a sequence of edges connecting the two vertices. A path may go either along or against the direction of the edges. A non-endpoint vertex $W$ on a path is said to be a collider if the edges preceding and following $W$ on the path both point to $W$, that is, $\rightarrow W \leftarrow \leftrightarrow W \leftarrow \rightarrow W \leftrightarrow$, or $\leftrightarrow W \leftrightarrow$. A vertex that is not a collider is a non-collider.

A path between $X$ and $Y$ is said to be unblocked given a set $Z$ (possibly empty), with $X, Y \notin Z$ if:
1. every noncollider on the path is not in $Z$
2. every collider on the path is in $An(Z)$ (Pearl 2009)

If there is no unblocked path between $X$ and $Y$ given $Z$, then $X$ and $Y$ are said to be $d$-separated given $Z$ (Pearl 2009). In this case, the model dictates that $X$ and $Y$ are independent given $Z$.

**Obtaining Constraints via Overidentification of Path Coefficients**

The correlation between two variables in an SEM can be easily expressed in terms of the path coefficients using the associated graph and Wright’s path-tracing rules (Wright 1921; Pearl 2013). These expressions can then be used to identify path coefficients in terms of the covariance matrix when the coefficients are identifiable. Consider the following model and its associated graph (Figure 1):

$$
\begin{align*}
V_1 &= \epsilon_1 \\
V_2 &= aV_1 + \epsilon_2 \\
V_3 &= bV_2 + \epsilon_3 \\
V_4 &= cV_3 + \epsilon_4 \\
\text{Cov}(\epsilon_2, \epsilon_4) &= d
\end{align*}
$$

Using the single-door criterion criterion (Pearl 2009) and Wright’s path-tracing rules, we identify two distinct expressions for $c$ in terms of the covariance matrix: $c = r_{XZ} = \frac{\sigma_{XZ}}{\sqrt{\sigma_{XX} \sigma_{ZZ}}}$ and $c = \frac{ab}{\sigma_{Z}} = \frac{\sigma_{XZ}}{\sigma_{Z}}$, where $r_{YXZ}$ is the regression coefficient of $Y$ on $X$ given $Z$ and $\sigma_{XYZ}$ is the covariance of $X$ and $Y$ given $Z$. As a result, we obtain the following constraint: $\frac{\sigma_{XZ}}{\sqrt{\sigma_{XX} \sigma_{ZZ}}} = \frac{\sigma_{XZ}}{\sigma_{Z}}$.

If violated, this constraint calls into question the lack of edge between $V_1$ and $V_4$.

**Finding Constraints using an Extended Half-Trek Criterion**

**Identification**

The half-trek criterion is a graphical condition that can be used to identify structural coefficients in an SEM, both recursive and non-recursive (Foygel, Draisma, and Drton 2012). In this section, we will paraphrase some preliminary definitions from (Foygel, Draisma, and Drton 2012) and present a generalization of the half-trek criterion that allows identifiability of potentially more coefficients in underidentified models.

**Definition 1.** (Foygel, Draisma, and Drton 2012) A half-trek, $\pi$, from $X$ to $Y$ is a path from $X$ to $Y$ that either begins with a bidirected arc and then continues with directed edges towards $Y$ or is simply a directed path from $X$ to $Y$.

If there exists a half-trek from $X$ to $Y$ we say that $Y$ is half-trek reachable from $X$. We denote the set of nodes that are reachable by half-trek from $X$, $\text{htr}(X)$.

**Definition 2.** (Foygel, Draisma, and Drton 2012) For any half-trek, $\pi$, let $\text{Right}(\pi)$ be the set of vertices in $\pi$ that have an outgoing directed edge in $\pi$ (as opposed to bidirected edge) union the last vertex in the trek. In other words, if the trek is a directed path then every vertex in the path is a member of $\text{Right}(\pi)$. If the trek begins with a bidirected edge then every vertex other than the first vertex is a member of $\text{Right}(\pi)$.

**Definition 3.** (Foygel, Draisma, and Drton 2012) A system of half-treks, $\pi_1, ..., \pi_m$, has no sided intersection if for all $\pi_i = \{\pi_{i1}, ..., \pi_{ik}\}$, $\pi_j = \{\pi_{j1}, ..., \pi_{jm}\}$, $\pi_{i1} \neq \pi_{j1}$ and $\text{Right}(\pi_i) \cap \text{Right}(\pi_j) = \emptyset$.

The half-trek criterion is a sufficient graphical condition for identifiability of the path coefficients of a variable, $v$. If satisfied, we can obtain a set of linear equalities among the covariance matrix and the coefficients of $v$. Further, this set of equations is linearly independent with respect to the coefficients of $v$, and we can therefore use standard methods for solving a set of linearly independent equations to identify the expressions for coefficients of $v$. Here, we modify the half-trek criterion to identify connected edge sets (defined below), which are subsets of a variable’s coefficients, rather than all of the variable’s coefficients at once. As a result, an unidentifiable edge will inhibit identification of the edges in its connected edge set only and not all of $v$’s coefficients. In this way, we increase the granularity of the criterion to determine identifiability of some variable coefficients even when they are not all identifiable.

**Definition 4.** Let $P_a, P_2, ..., P_k$ be the unique partition of $\text{Pa}(v)$ such that any two parents are placed in the same...
subset, $P_{av}$, whenever they are connected by an unblocked path. A connected edge set with head $v$ is a set of edges from $P_{av}$ to $v$ for some $i \in \{1, 2, \ldots, k\}$.

In Figure 2, there are two connected edge sets with head $V_7$. One is $\{(V_4, V_7)\}$ and the other is $\{(V_5, V_7), (V_6, V_7)\}$. $V_4$ has no path to other parents of $V_7$ while $V_5$ and $V_6$ are connected by a bidirected arc.

**Definition 5. (Edge Set Half-TrekCriterion)** Let $E$ be a connected edge set with head $v$. A set of variables $Y$ satisfies the half-trek criterion with respect to $E$, if

(i) $|Y| = |E|$  
(ii) $Y \cap (v \cup \text{Sib}(v)) = \emptyset$ and  
(iii) There is a system of half-treks with no sided intersection from $Y$ to $Ta(E)$.

When it is clear from the context, we will simply refer to the edge set half-trek criterion as the half-trek criterion. An edge set, $E$, is identifiable if there exists a set, $Y_E$, that satisfies the half-trek criterion with respect to $E$. However, $Y_E$ must consist only of "allowed" nodes. Intuitively, a node, $y$, is allowed for $E$ if it is either not half-trek reachable from $He(E)$ or any of $y$'s coefficients that lie on an unblocked path between $He(E) \cup Ta(E)$ and $y$ are themselves identifiable. We define this notion formally below.

**Definition 6.** Let $ES$ be the set of connected edge sets in the causal graph, $G$. We say that $a$ is an HT-allowed node for edge set $E_v$ with head $v$ if $a$ is not half-trek reachable from $v$ or both of the following conditions are satisfied:

(i) There exists an ordering on $ES$, $\prec$, and a family of subsets $(Y_E)_{E \in ES}$, one subset for each $E \prec E_v$, such that $Y_E$ satisfies the half-trek criterion with respect to $E$ and $E_i \prec E_j$ for $E_i, E_j \prec E_v$ whenever $He(E_i) \subseteq \text{htr}(He(E_j)) \cap Y_E_i$ and there exists an unblocked path between $Ta(E_i)$ and $He(E_j) \cup Ta(E_j)$.

(ii) The edge set of any edges belonging to $a$ that lie on a half-trek from $v$ to $a$ are ordered before $E_v$.

Let $CE(y, E)$ be the connected edge sets containing edges belonging to $y$ that lie on an unblocked path from $y$ to $He(E) \cup Ta(E)$. Now, define $\text{Allowed}(E, \text{IEdgeSets}, G)$, used in Algorithms 1 and 2, as the set $(V \setminus \text{htr}(He(E))) \cup \{y | CE(y, E) \in \text{IEdgeSets}\}$ for some set of connected edge sets, IEdgeSets. Intuitively, $\text{Allowed}(E, \text{IEdgeSets}, G)$ contains the set of nodes that have been determined to be allowable for $E$ based on the edge sets that have been identified by the algorithm so far.

If $Y$ is a set of allowed variables for $E$ that satisfies the half-trek criterion with respect to $E$, we will say that $Y$ is an HT-admissible set for $E$.

**Theorem 1.** If a HT-admissible set for edge set $E$ with head $v$ exists then $E$ is identifiable. Further, let $Y_E = \{y_1, \ldots, y_k\}$ be a HT-admissible set for $E$, $Ta(E) = \{p_1, \ldots, p_k\}$, and $\Sigma$ be the covariance matrix of the model variables. Define $A$ as

$$A_{ij} = \begin{cases} 0, & \text{if } y_i \notin \text{htr}(v) \text{ and } y_j \notin \text{htr}(v) \\ \Sigma_{y_i, y_j}, & \text{if } y_i \in \text{htr}(v), y_j \in \text{htr}(v) \end{cases}$$

and $b$ as

$$b_i = \begin{cases} 0, & \text{if } y_i \notin \text{htr}(v) \\ \Sigma_{y_i, v}, & \text{if } y_i \in \text{htr}(v) \end{cases}$$

Then $A$ is an invertible matrix and $A \cdot A_{Ta(E), v} = b$.

*Proof.* The proof for this theorem is similar to the proof of Theorem 1 (HTC-identifiability) in (Foygel, Draisma, and Drton 2012). Rather than giving the complete proof, we give some brief explanation for why our changes are valid. We made two significant changes to the half-trek criterion. First, we identify connected edge sets rather than the entire variable. Since different edge sets are unconnected, the paths from a half-trek admissible set, $Y_E$, to $v = He(E)$ travel only through the coefficients of $E$ and no other coefficients of $v$. As a result, $A \cdot A_{Ta(E), v} = b$ is still valid. Additionally, $A$ is still invertible due to the lack of sided intersection in $Y_E$.

Second, if $y \in Y_E$ is half-trek reachable from $v$, we do not require $y$ to be fully identified but only the edges of $y$ that lie on paths between $He(v) \cup Ta(v)$ and $y$. Let $E_y$ be the edges of $y$ and $E_{\text{htr}(v)} \subseteq E_y$ be the set of $y$'s edges that do not lie on any half-trek from $v$ to $y$. With respect to the matrix, $A$, $(I - \Lambda)^T \Sigma y, E_{Ta(E)}$ is still obtainable since $\Sigma_{Ta(E_{\text{htr}(v)}, E_{Ta(E)})} = 0$. We do not need to identify the coefficients of $E_{\text{htr}(v)}$ since they will vanish from $A$. Similarly, they vanish from $b$ since $\Sigma_{Ta(E_{\text{htr}(v)}, v)} = 0$.

If a connected edge set $E$ is identifiable using Theorem 1 then we say that $E$ is HT-identifiable.

Using Figure 2 as an example, we consider the coefficients of the two connected edge sets with head $V_7$, $\{d\}$ and $\{e, f\}$. The coefficients, $e$ and $f$, are not HT-identifiable, but $d$ is. $\{V_3\}$ is an HT-admissible set for $e$ even though $V_3 \in \text{htr}(V_2)$ since $V_3$'s only coefficient, $b$, is identifiable using $\{V_2\}$. Therefore, each coefficient of $V_3$ that is reachable from $V_7$ is identifiable and it is allowed to be in the set $Y_d$. Since coefficients $e$ and $f$ are not HT-identifiable, the half-trek criterion of (Foygel, Draisma, and Drton 2012) simply states that the variable $V_2$ is not identifiable and fails to address the identifiability of $d$.

Finding a HT-admissible set for a connected edge set, $E$, with head, $v$, from a set of allowed nodes, $A_G$, can be accomplished by modifying the max-flow algorithm described in (Foygel, Draisma, and Drton 2012). First, we construct a graph, $G_f(E, A)$, with at most $2|V| + 2$ nodes and $3|V| + |D| + |B|$ edges, where $D$ is the set of directed edges and $B$ is the set of bidirected edges in the original graph, $G$. The graph, $G_f(E, A)$, is constructed as follows:

First, $G_f(E, A)$ is comprised of three types of nodes:

(i) a source $s$ and a sink $t$

(ii) a "left-hand copy" $L(a)$ for each $a \in A$

(iii) a "right-hand copy" $R(w)$ for each $w \in V$

The edges of $G_f(e, A)$ are given by the following:

(i) $s \rightarrow L(a)$ and $L(a) \rightarrow R(a)$ for each $a \in A$

(ii) $L(a) \rightarrow R(w)$ for each $a \leftrightarrow w \in B$
(iii) \( R(w) \rightarrow R(u) \) for each \( w \rightarrow u \in D \)

(iv) \( R(w) \rightarrow t \) for each \( w \in Ta(E) \)

Finally, all edges have capacity \( \infty \), the source, \( s \), and sink, \( t \), have capacity \( \infty \), and all other nodes have capacity 1. Intuitively, a flow from source to sink represents a half-trek in the original graph, \( G \), while the node capacity of 1 ensures that there is no sided intersection. The only difference between our construction and that of (Foygel, Draisma, and Drton 2012) is that instead of attaching parents of \( v \) to the sink node in the max-flow graph, we attach only nodes belonging to \( Ta(E) \) to the sink node.

Once the graph, \( G_f(E, A) \), is constructed, we then determine the maximum flow using any of the standard maximum flow algorithms. The size of the maximum flow indicates the number of variables that satisfy conditions (ii) and (iii) of the Edge Set Half-Trek Criterion. Therefore, if the size of the flow is equal to \( |E| \) then \( E \) is identifiable. Further, the “left-hand copies” of the allowed nodes with non-zero flow are the nodes that can be included in the HT-admissible set, \( Y_E \). Let MaxFlow(\( G_f(E, A) \)), to be used in Algorithms 1 and 2, return the “left-hand copies” of the allowed nodes with non-zero flow.

### Theorem 2.

Given a causal graph, \( G = (V, D, B) \), a connected edge set, \( E \), and a subset of “allowed” nodes, \( A \subseteq V \setminus (\{v\} \cup \text{sib}(v)) \), there exists a set \( Y \subseteq A \) satisfying the half-trek criterion with respect to \( E \) if and only if the flow network \( G_f(E, A) \) has maximum flow equal to \( |Ta(E)| \). Further, the nodes in \( L(A) \) of the flow graph, \( G_f(E, A) \) with non-zero flow satisfy conditions (ii) and (iii) of the Edge Set Half-Trek Criterion, and therefore, comprise a HT-admissible set for \( E \) if the maximum flow is equal to \( |Ta(E)| \).

The proof for this theorem is omitted since it is very similar to the proof for Theorem 6 in (Foygel, Draisma, and Drton 2012). Algorithm 1 gives a method for identifying coefficients in a linear SEM, even when the model is under-identified.

### Overidentifying Constraints

Once we have identified a connected edge set, \( E \), using the half-trek criterion, we can obtain a constraint if there exists an alternative HT-admissible set for \( E \), \( Y_E \neq Y_D \), since \( Y_E \) can then be used to find distinct expressions for some of the path coefficients associated with \( E \). Further, these distinct expressions are derived from different aspects of the model structure and, therefore, are derived from logically independent sets of assumptions specified by the model. As a result, an equality constraint is obtained by setting both expressions for a given coefficient equal to one another. The following lemma provides a condition for when such a set exists.

**Lemma 1.** Let the vertex set, \( Y_E \), be an HT-admissible set for connected edge set, \( E \), and let \( v \) be the head of \( E \). An alternative HT-admissible set for \( E \), \( Y_E' \neq Y_E \), exists if there exists a vertex, \( w \notin Y_E \), such that

1. there exists a half-trek from \( w \) to \( Ta(E) \),
2. \( w \notin (v \cup \text{sib}(v)) \), and
3. if \( w \in \text{htr}(v) \), the connected edge sets containing edges belonging to \( w \) that lie on unblocked paths between \( w \) and \( He(E) \cup Ta(E) \) are HT-identifiable.

**Proof.** Let \( \pi_w \) be any half-trek from \( w \) to \( Ta(E) \). Clearly, \( \{\pi_w\} \cup \Pi \) has a sided intersection since there are more half-treks in \( \{\pi_w\} \cup \Pi \) than vertices in \( Ta(E) \). Now, let \( \pi \) be the first half-trek that \( \pi_w \) intersects and \( x \) be the first vertex that they share. More precisely, if we order the vertices in \( \pi_w \) so that \( w \) is the first vertex, \( t \in Ta(E) \) the last, and the remaining vertices ordered according to the path from \( w \) to \( t \) then \( x \) is the first vertex in the set \( (\bigcup_{i \in \Pi} \text{Right}(\pi_i)) \cap \text{Right}(\pi_w) \) and \( \pi \) is the half-trek in \( \Pi \) such that \( x \in \text{Right}(\pi) \). Note that \( \pi \) is unique because \( \Pi \) has no sided intersection. Now, let \( \pi_w \) be the half-trek from \( w \) to \( Ta(E) \) that is the same as \( \pi_w \) until vertex \( x \) after which it follows the path of \( \pi \). \( \pi_w \) is a half-trek from \( w \) to \( v \) and \( \Pi' = \Pi \setminus \{\pi\} \cup \{\pi_w\} \) has no sided intersection. Now if we let \( z \) be the first vertex in \( \pi \) then it follows that \( Y_{E'} = Y_E \setminus \{z\} \cup \{w\} \) satisfies the half-trek criterion with respect to \( E \). 

Note that this proof also shows how to obtain the alternative set \( Y_{E'} \) once a variable \( w \) that satisfies Lemma 1 is identified.
found. In Figure 1, \((V_3, V_4)\) can be identified using either 
\(Y = \{V_3\}\), which yields \(c = \sigma_{13,2}\) or \(Y' = \{V_1\}\), which yields \(c = \frac{\sigma_{14}}{\sigma_{12}}\). Both sets satisfy the half trek criterion and 
yield different expressions for \(c\) giving the same constraint as before, \(\frac{\sigma_{14}}{\sigma_{12}} = \frac{\sigma_{14}}{\sigma_{12}}\).

While overidentifying constraints can be obtained by 
identifying the edge set \(E\) using different HT-admissible sets, 
there is actually a more direct way to obtain the con-
straint. Let \(T a(E) = \{p_1, ..., p_k\}\), and \(\Sigma\) be the covariance 
matrix of the model variables. Define \(a_w\) as

\[ \mathbf{a}_w = \begin{cases} \begin{array}{ll} (I - \Lambda)^T \Sigma & \text{if } w \in htr(v), \\ \Sigma_{w,p_j} & \text{if } w \notin htr(v), \end{array} \end{cases} \]

and \(b_w\) as

\[ \mathbf{b}_w = \begin{cases} \begin{array}{ll} (I - \Lambda)^T \Sigma & \text{if } w \in htr(v), \\ \Sigma_{w,v} & \text{if } w \notin htr(v), \end{array} \end{cases} \]

From Theorem 1, we have that \(A \cdot \Lambda_{T a(E),v} = b\). Simi-
larly, \(a_w^T \cdot \Lambda_{T a(E),v} = b_w\). Now, \(a_w = d^T \cdot A\) for some 
vector of constants \(d\) since \(A\) has full rank. As a result, \(b_w = d^T \cdot b\), giving us the constraint \(a_w^T A^{-1} b = b_w\).

Clearly, if we are able to find additional variables that sa-
fisfy the conditions given above for \(w\), we will obtain ad-
ditional constraints. Constraints obtained using the above 
method may or may not be conditional independence con-
straints. We refer to constraints identified using the half-
trek criterion as **HT-overidentifying constraints.** Algorithm 2 
gives a procedure for systematically discovering HT-
overidentifying constraints.

We use Figure 2 as an illustrative example of Algorithm 2. 
First, \(b\) is identifiable using \(Y_5 = \{V_2\}\), and \(V_1\) satisfies 
the conditions of Lemma 1 giving the constraint \(\sigma_{23} = \frac{\sigma_{14}}{\sigma_{12}}\), 
which is equivalent to the conditional independence con-
straint that \(V_1\) is independent of \(V_3\) given \(V_2\). Next, \(d\) is 
identifiable using \(Y_4 = \{V_5\}\), which then allows \(a\) to be 
identifiable using \(\{V_7\}\). Since \(a\) is identifiable, \(\{V_2\}\) is HT-
admissible for \(c\), allowing \(c\) to be identified. \(\{V_2\}\) also satis-
fies the conditions of Lemma 1 for \(d\) giving the constraint:

\[-\sigma_{23} \sigma_{27} + \sigma_{37} = \frac{\sigma_{24}}{\sigma_{23}} \sigma_{23} \sigma_{27} - (\frac{\sigma_{24}}{\sigma_{23}} \sigma_{23} \sigma_{27} - \frac{\sigma_{24}}{\sigma_{23}} \sigma_{23} \sigma_{27} - \frac{\sigma_{24}}{\sigma_{23}} \sigma_{23} \sigma_{27} - \sigma_{24}) \]

Note that \(d\) is not identifiable using other known methods 
and, as a result, this constraint is not obtainable using the 
methods of (Brito 2004) or (McDonald 2002). Lastly, \(a\) is also 
overidentified using \(\{V_1\}\) yielding the constraint:

\[-\sigma_{14} \sigma_{23} \sigma_{27} - \sigma_{14} \sigma_{37} + \sigma_{17} = \frac{-c \sigma_{13} + \sigma_{24}}{\sigma_{24} \sigma_{23} \sigma_{27} - \sigma_{24} \sigma_{23} \sigma_{27} - \sigma_{24} \sigma_{23} \sigma_{27} - \sigma_{24}} \]

where

\[ c = \frac{\sigma_{14} \sigma_{23} \sigma_{27} - \sigma_{14} \sigma_{37} + \sigma_{17}}{\sigma_{24} \sigma_{23} \sigma_{27} - \sigma_{24} \sigma_{23} \sigma_{27} - \sigma_{24} \sigma_{23} \sigma_{27} - \sigma_{24}} \]

Finally, suppose an overidentifying constraint is violated. 
How can the modeler use this information to revise his or her 
assumptions? Consider a connected edge set \(E\) with head 
v and a HT-admissible set \(Y_E\). If a variable \(w\) satisfies the 
conditions of Lemma 1 then the set \(Y_E \cup \{w\}\) must have at 
least one variable that is not a parent of \(v\). Let \(K = Y_E \setminus 
(Pa(v) \cup \{w\})\). If the overidentifying constraint, \(\mathbf{b}_w = \mathbf{a}_w \cdot \mathbf{A}^{-1} \cdot \mathbf{b}\), is violated then the modeler should consider adding 
an edge, either directed, bidirected, or both, between \(K\) to \(v\) 
since doing so eliminates the constraint.

### Algorithm 2 Find Constraints

**Input:** \(G = (V, D, B), ES\)

**Initialize:** \(\text{IDEdgeSets} \leftarrow \emptyset\)

**repeat**

for each \(E \in ES\) do

\(A_E \leftarrow \text{Allowed}(E, \text{IDEdgeSets}, G)\)

\(Y_E \leftarrow \text{MaxFlow}(G_i(E, A))\)

if \(|Y_E| = |Ta(E)|\) then

if \(E \notin \text{IDEdgeSets}\) then

Identify \(E\) using Theorem 1

\(\text{IDEdgeSets} \leftarrow \text{IDEdgeSets} \cup E\)

end if

for each \(w\) in \(A_E \setminus Y_E\) do

if \(v \in htr(w)\) then

Output constraint: \(\mathbf{b}_w = \mathbf{a}_w \cdot \mathbf{A}^{-1} \cdot \mathbf{b}\)

end if

end for

end if

end for

until one iteration after all edges are identified or no new 
edges have been identified in the last iteration

### Conclusion

In this paper, we extend the half-trek criterion in order to 
identify additional coefficients when the model is underiden-
tified. We then use our extended criterion to systematically 
discover overidentifying constraints. These local constraints 
can be used to test the model structure and potentially be 
incorporated into constraint-based discovery methods.
